2171 DEVELOPMENT OF TRANSPORTATION IN THE UNITED STATES.
By **J. E. Teal** 1

Discussion:
By Fred Lavis 24
William J. Wilgus 25
Joseph B. Eastman 29
J. L. Campbell 30
W. W. Crosby 32
W. B. Irwin 34
F. R. Schanck 36
J. E. Teal 40

2172 STABILITY OF GRANULAR MATERIALS.
By **R. E. Glover and F. E. Cornwell** 46

Discussion:
By R. G. Hennes 64
Stanley U. Benscoter 65
A. Hrennikoff 69
D. P. Krynine 72
R. E. Glover and F. E. Cornwell 78

2173 DRAINAGE OF LEVEED AREAS IN MOUNTAINOUS VALLEYS.
By **Gordon R. Williams** 83

Discussion:
By Merrill Bernard 97
L. K. Sherman 98
C. O. Clark 100
W. W. Horner 103
Walter T. Wilson 108
W. B. Langbein 109
Gordon R. Williams 112

2174 TIMBER FRICTION PILE FOUNDATIONS.
By **Frank M. Masters** 115

Discussion:
By E. H. Connor 141
Glenn B. Woodruff 142
Jacob Feld 143
G. G. Greulich 144
G. S. Paxson 145
Raymond D. Mindlin 147
John W. Solomon 149
A. E. Cummings 162
Frank M. Masters 170

2175 ALLOCATION OF THE TENNESSEE VALLEY AUTHORITY PROJECTS.
By **Theodore B. Parker** 174

Discussion:
By Malcolm Elliott 188
E. L. Chandler 189

No. Page

Eugene L. Grant 202
Sherman M. Woodward 203
Albert R. Arledge 205
C. W. Watchorn and F. A. Allner 210
Theodore B. Parker 215

2176 BENDING MOMENTS IN THE WALLS OF RECTANGULAR TANKS.
By **Dana Young** 217

Discussion:
By I. K. Silverman 231
Dana Young 232

2177 DESIGN OF SIGN LETTER SIZES.
By **Adolphus Mitchell and T. W. Forbes** 233

Discussion:
By Guy Kelcey 243
Charles M. Noble 244
Adolphus Mitchell and T. W. Forbes 245

2178 LATERAL STABILITY OF UNSYMMETRICAL I-BEAMS AND TRUSSES IN BENDING.
By **George Winter** 247

Discussion:
By Robert K. Schrader 261
H. N. Hill 264
George Winter 266

2179 REDUCTION OF MINERAL CONTENT IN WATER WITH ORGANIC ZEOLITES.
By **R. F. Goudey** 269

Discussion:
By James M. Montgomery 281
George L. Davenport 283
Robert Spurr Weston 284
Harvey F. Ludwig and Russell G. Ludwig 286

2180 UNUSUAL EVENTS AND THEIR RELATION TO FEDERAL WATER POLICIES.
By **W. G. Hoyt** 290

Discussion:
By Edward H. Sargent 304
Dana M. Wood 304
James S. Sweet 306
J. L. Campbell 307
David J. Guy 309
Albert S. Fry 312
W. G. Hoyt 314

2181 EFFECT OF VARIATION OF ELASTIC CHARACTERISTICS ON STATIC UNKNOWNS.
By **A. Hrennikoff** 317

Discussion:
By A. H. Finlay 340
Stefan J. Fraenkel 343
Joseph A. Wise 345
A. Hrennikoff 350

2182 BASIC ECONOMIC CONSIDERATIONS AFFECTING SINGLE AND MULTIPLE PURPOSE PROJECTS.
By **Otis M. Page** 353

Discussion:
By G. B. Pillsbury 363

No. Page

2183 ANALYTICAL AND EXPERIMENTAL METHODS IN ENGINEERING SEISMOLOGY.
By **M. A. Biot** 365

Discussion:
By George R. Rich 386
N. J. Hoff 388
Merit P. White 390
N. H. Heck 394
Frank Neumann 395
Jacob Feld 397
George W. Housner 398
Homer M. Hadley 402
Robert E. Glover 405
M. A. Biot 405

2184 HYDRODYNAMICS OF MODEL STORM SEWER INLETS APPLIED TO DESIGN.
By **G. S. Tapley** 409

Discussion:
By Ralph W. Powell 444
G. S. Tapley 445

2185 MECHANICS OF CREEP FOR STRUCTURAL ANALYSIS.
By **Joseph Marin** 453

Discussion:
By A. Hrennikoff 470
C. A. P. Turner 472
Ralph W. Stewart 477
Joseph Marin 479

2186 PROFILE CURVES FOR OPEN-CHANNEL FLOW.
By **Dwight F. Gunder** 481

Discussion:
By Carl Rohwer 489
C. J. Posey 489
J. C. Stevens 492
Boris A. Bakhmeteff and Nicholas V. Feodoroff 492
Hunter Rouse 502
Dwight F. Gunder 504

2187 THE GREASE PROBLEM IN SEWAGE TREATMENT.
By **Almon L. Fales and Samuel A. Greeley** 507

Discussion:
By Arthur D. Weston 525
Harvey F. Ludwig 535
W. S. Mahlie 537
Denis Dickinson 537
Charles R. Velzy 538
F. M. Dawson 539
Almon L. Fales and Samuel A. Greeley 541

2188 DESIGN OF ST. GEORGES TIED ARCH SPAN.
By **J. M. Garrelts** 543

Discussion:
By R. W. Abbett 555
Jacob Karol 555
Alexander Dodge 558
Carlos A. Bejarano 566
A. A. Eremin 568

DEVELOPMENT OF TRANSPORTATION IN THE UNITED STATES

By J. E. Teal,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Fred Lavis, William J. Wilgus, Joseph B. Eastman, J. L. Campbell, W. W. Crosby, W. B. Irwin, F. R. Schanck, and J. E. Teal.

Synopsis

The first railroad chartered in the United States was the Baltimore and Ohio, in 1828, and the story of the development of the railroads that followed, which made possible the United States as it exists today, is intensely interesting. Other forms of transportation have come into being, and some have grown to a point where they are having a decided influence on the social and economic environments of every community in the Nation. These agencies of transportation, under present conditions, are all competitive with each other, and certain economic influences have developed that apparently have resulted in unfair competition between them.

With the importance of the issues in mind, the writer has endeavored, in this paper, to sketch the history of transportation during the past one hundred or more years, to outline briefly some of the economic conditions, and to discuss a few of the pertinent factors involved. An effort has been made to correlate facts and data pertaining to the subject, which is now a transportation problem so vital and so far-reaching that a sound national economy may depend on its solution.

Railway Transportation

During the past 113 years, railway development in the United States passed through several distinct stages. The "First Stone" of the Baltimore and Ohio Railroad was laid on July 4, 1828, at which ceremony the venerable Charles Carroll, of Carrollton (Va.), remarked:

> "I consider this among the most important acts of my life, second only to the signing of the Declaration of Independence, even if indeed it be second to that."

Note.—Published in December, 1941, *Proceedings*.

[1] Prin. Roadway Engr., Board of Investigation and Research, Washington, D. C.

From that date to 1850 was a period of exploration, both in the matter of developing road, equipment, and plant facilities, and in the methods of finance and management.

The next forty years was a period of very rapid railway expansion. The railway systems had been pushed west across the Allegheny Mountains to Chicago, Ill., and the Union Pacific and the Central Pacific railroads had been completed by 1869. Railway development was rapid during the period leading to the depression of 1873. The decade 1880 to 1890 witnessed an increase in railway lines aggregating more than 70,000 miles, when a number of transcontinental lines were constructed.

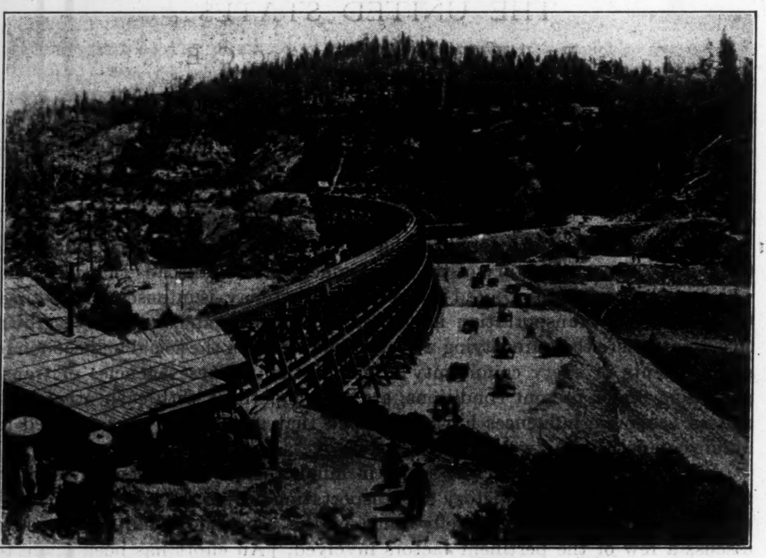

FIG. 1.—RAILROAD DEVELOPMENT WAS RAPID DURING THE PERIOD LEADING TO THE DEPRESSION OF 1873

During this period of rapid railway construction, public authorities and federal, state, and local governments became convinced that the railways were indispensable to the prosperity of the Nation. Railway construction was encouraged by means of federal land grants and financial subsidies until about 1871. Some financial aid was contributed after that year.

From 1890 to the period of federal control (1917 to 1920) might be considered as the finishing period of the railway plant. Railway construction consisted mainly of the building of feeder and cross lines or new branch lines—the rounding out of the railway system as it is known today. Railway mileage was increased from 163,597 in 1890 to the peak of 254,251 in 1916, but this had receded to 235,064 miles in 1939. Track mileage reached a maximum of 429,883 miles in 1930, declining to 408,350 miles in 1939; thousands of miles of branch and feeder lines have become obsolete.

The last period, covering two decades, is of great significance in the railway picture; it begins when highway transportation entered upon a new era of development. As the result of competition growing out of common-carrier service on the highways, the revival of waterways, the expansion of pipe-line transportation, and the coming of the airplane, the railway industry has had to "tighten its belt" in order to meet financial obligations.

Railroad Operating Results Since 1920

The total property investment in Class I railways amounted to $26,527,000,000 in 1930, decreasing to $26,131,000,000 at the end of 1939. Peak revenues reached the total of $6,383,000,000 in 1926, declined to an average of $3,622,000,000 per yr from 1931 to 1937, and were $3,995,000,000 in 1939, a 13-yr decrease of 37%.

Net income, after fixed charges, reached its peak in 1929, with a total of $897,000,000, but only averaged $35,000,000 per annum from 1931 to 1937; in 1938 there was a net deficit of $129,000,000, with a net gain of only $93,000,000 in 1939. Railway taxes increased from $276,000,000 in 1921 to $356,000,000 in 1939, or 29%; and taxes per one dollar of revenue increased from 5.0¢ in 1921 to 8.9¢ in 1939, or 78%. The rate of return earned by the railroads on their investment in transportation property averaged 4.81% in 1929, 1.67% for the years 1931 to 1937, 1.43% in 1938, and 2.26% in 1939, a 10-yr decrease of 53%.

Railroad freight traffic reached 447,000,000,000 ton-miles, its peak, in 1929, averaged 292,000,000,000 ton-miles from 1931 to 1937, and 333,438,000,000 ton-miles in 1939, a 10-yr decrease of 25%. Railroad passenger traffic reached its peak in 1920, when 46,800,000,000 passenger-miles were handled, declined to an average of 19,900,000,000 from 1931 to 1937, and amounted to 22,651,000,000 in 1939, a 19-yr decrease of 52%.

Railroad freight rates declined from 12.75 mills per ton-mile in 1921 to an average of 9.96 mills from 1931 to 1937, and 9.74 mills per ton-mile in 1939, an 18-yr decrease of 23%. Average revenue per passenger-mile declined from a maximum of 3.86¢ in 1921 to 2.033¢ from 1931 to 1937, and 1.839¢ in 1939, an 18-yr decrease of 52%. Competition has been an important factor in the downward trend in railroad freight and passenger rates.

Railroad employment declined from the peak figure of 2,022,000 in 1920 to an average of 1,063,000 from 1931 to 1937, and 988,000 in 1939, a 19-yr decrease of 51%.

Because of the failure of many carriers to meet their interest charges, the credit of the railroad industry in general has been greatly impaired, and must be recouped in the future. The meager financial results of railroad operations for 1938, amounting to 1.43% return on the investment, were secured by heavy reduction in maintenance and other expenditures, some of which must be made up at some future date. Closely related to the subject of maintenance is the decrease in ability of the railroads to contribute to the national economy in the form of purchases of the products of manufacturers and other industry.

The gross capital expenditures made by the railroads for the period 1921 to 1930 were an average of $773,000,000 per annum. For the period 1931 to

1939 this average amounted to only $262,000,000, or a decrease of $511,000,000, or 66%, per annum. Comparing the purchases of fuel, material, and supplies during the same periods, the average annual expenditure was reduced from $1,384,000,000 for the first period to $660,000,000 for the second period, a decrease of $724,000,000, or 52% per annum. These statistics show that under normal conditions the railroads are heavy consumers of the products of other industries and are, therefore, an important factor in the Nation's business. Also, the capability of the railroads to buy equipment and other supplies, and to foster general employment, has been seriously impaired in recent years.

More than 75,000 miles of railroad lines, or about one third of all railroad mileage, are now in the hands of receivers or trustees. This is the largest proportion of rail mileage in bankruptcy ever recorded in the history of the United States.

It is only necessary to note the many improvements that have developed in rail transportation during the two decades 1920–1940, and more particularly, the latter of the two. Every one knows of the modern, streamlined, air-conditioned, high-speed passenger trains, and the faster freight, including the pickup and delivery services.

INLAND WATERWAY TRANSPORTATION

The history of inland waterway transportation, of course, antedates that of railroad transportation. Rivers and canals were among the principal channels of transportation in the United States until the close of the Civil War. In Virginia, the James River Company, organized by George Washington and others, as a stock company, in 1785, had as its object the construction of a canal from the tidal basin of the James River at Richmond, Va., following that river to Clifton Forge, Va., and across the Allegheny Mountains, by highway, to the Kanawha River, a tributary of the Ohio River in West Virginia. The canal was completed for a distance of 200 miles, when financial troubles stopped construction. The property was later taken over by the predecessor of The Chesapeake and Ohio Railway Company. By the close of 1825, the Erie Canal had been completed between the Hudson River and Lake Erie, 351 miles, and in 1828 the Chesapeake and Ohio Canal was under construction from the tidal basin of the Potomac River at Washington, D. C., for a distance of 186 miles, following the Potomac River to Cumberland, Md.

Canal construction spread very rapidly, not only in those states along the eastern seaboard that were in need of lines of communication with the Middle West, but also within the Western States. Following the Civil War, in 1865, the development of railways attracted much of the commerce that formerly moved by water. The railways also created new commerce in many areas not served by rivers, following which traffic on the rivers and canals declined to a condition of little importance.

The first turnpike roads were built in the United States with the view that the full cost of transportation should be borne by the shipper. Likewise, it was the intention to charge tolls for the use of the canals; but returns from this source rarely were sufficient to cover both capital charges and maintenance expenses. The Pennsylvania canals were a complete financial failure. The

New York system of inland waterways, including the Hudson River and the Erie-Champlain canal, made a better showing, but had to be (and still are) supported substantially by general taxation. The total cost of canals to the people of New York from the beginning to 1929 has amounted to more then $346,000,000. From 1930 to 1940, inclusive, the total expense aggregated $109,195,000, or an average of $9,927,000 per annum, divided thus: $31,398,000, or $2,854,000 per annum, for operation and maintenance, and $77,797,000, or $7,073,000 per annum, for carrying charges on construction cost, computed at 4% per annum. This brings the grand total of expenditures, to 1940, to $455,195,000. Annual credit for revenue received by the commissioner of canals and waterways for various services amounted to $607,000 for 1940.

By 1885, the rivers and canals had lost most of the high-grade traffic. However, low-grade traffic, such as sand, gravel, and coal, continued to move in fairly large quantities for a longer period. By the end of the century, with the exception of coal traffic on the Monongahela and Ohio rivers, canal and river transportation was unimportant.

FIG. 2.—THE INLAND WATERWAYS RENAISSANCE RECEIVED A GREAT STIMULUS DURING THE FIRST WORLD WAR

The inland waterways renaissance, which began in the last decade of the nineteenth century, received a great stimulus during the first World War, and since the war has been carried forward with the assistance of fostering legislation and the spur of many government officials, individuals, and organizations. To bring this question down to date, it suffices to state that the report by the chief of engineers of the United States Army for 1939 shows that a total of $3,637,528,923 has been spent or authorized on the construction and maintenance of waterways projects to June 30, 1939, of which approximately $2,655,000,000 has been spent or authorized for river and harbor navigation projects. Of this amount, approximately $1,123,000,000 was on the Mississippi River system, $517,000,000 for other waterways, and the remainder for seacoast and lake harbors and channels and intercoastal canals. The total mileage of inland waterways, according to the Board of Engineers for Rivers and Harbors, as of June 15, 1935, aggregated 26,406, divided as follows:

Inland waterways	Route mileage
Atlantic Coast rivers	5,263
Gulf Coast rivers, including the Mississippi River system	17,381
Pacific Coast rivers	1,796
Intercoastal waterways	1,966
Total	26,406

Of the total mileage, 15,688 miles have a depth of less than 6 ft; 5,394 miles have depths ranging between 6 ft and 9 ft; 4,746 miles have depths ranging from 9 ft to 12 ft; and 1,578 miles have depths greater than 12 ft.

TABLE 1.—WATER-BORNE TONNAGE

Year	SHORT TONS (THOUSANDS)		
	Great Lakes	Other	Total
1920	98,751	125,400	224,151
1925	113,644	204,569	318,213
1930	115,727	226,760	342,487
1935	89,356	225,917	315,273
1936	122,788	276,264	399,052
1937	143,356	313,287	456,643
1938	82,480	277,755	360,235

The total tonnage of water-borne commerce on the Great Lakes, and on rivers, canals, and connecting channels in the United States, after eliminating the known duplications, is shown in Table 1 for the calendar years 1920 through 1938. From this table it will be seen that the tonnage other than on the Great Lakes has increased from 125,400,000 tons in 1920 to 277,755,000 tons in 1938, an increase of 121%.

The total ton-mileage on inland waterways of the United States during 1938, exclusive of the Great Lakes, was 17,742,506,538. The total ton-mileage on the Great Lakes was 49,004,019,901, which, together with that on the rivers, canals, and connecting channels, makes a total ton-mileage of 66,746,526,439. Computed on the basis of 4.46 mills per ton-mile (average for Inland Waterway Corporation 1924 to 1935), the expense to the shippers using rivers, canals, and connecting channels for transporting 17,742 million tons one mile in 1938 would be approximately $79,000,000. The cost of owning and maintaining the waterways, of course, is borne by the federal government.

HIGHWAY TRANSPORTATION

The development of highways in the United States has passed through three periods, each characterized by usage of a distinct character. In the first period, extending to about the middle of the nineteenth century, the initiative in furnishing major highway routes was taken by the federal government. This was gradually relinquished, until about 1856 all federal jurisdiction over the national highway routes had been assumed by the states through which the routes passed. During this time a number of states had found the development of subsidiary highway routes to be burdensome and had placed some of them on a commercial basis by granting charters to individuals or companies, permitting them to build and operate toll roads. The states, however, participated in the cost of these projects and retained the right to regulate them.

Prior to 1892 the development in the field of highway transportation involved no particular complex problems of public policy. Both the building of the roads and the building of the motor vehicles were passing through experimental phases. The use of the public highways for purely commercial purposes had not attained sufficient importance to cause any concern on the part of the established carriers.

The second period in the development of the highway transportation as it exists today embraces the one of rapid railroad building, extending to about 1900. As the railroad mileage expanded, the use and necessity of the highways decreased to a position of minor importance. As transportation over public roads became unnecessary and unprofitable except for short distances, the building and maintenance of these roads were reduced to a matter of local importance only and consequently were left to the small political subdivisions, such as the county, township, and road district. It follows that from the middle to the end of the nineteenth century only a small proportion of highway travel passed beyond the boundaries of local political subdivisions, and the administration and financial responsibility for furnishing highway facilities thus narrowed down to such areas.

The year 1900 marks the beginning of the third period, which is characterized by a very rapid increase in the use of the highways. As the automobile developed, it soon became apparent that transportation on the highways for longer distances was possible, resulting in the creation of traffic that bore little or no relation in point of origin and destination to the political areas through which it passed. Such traffic was of an entirely different character than the type that moved wholly within the local subdivisions. It was also realized that the cost of highways required by these different types of traffic could not with equity be assessed entirely against the local property owners, but that a certain part of the cost should be borne by the taxpayers at large.

From 1900 to 1920 the development of the highway was somewhat similar to the evolution of the automobile—that is, as it developed, it passed through various experimental stages as to types of materials used in its construction. As the volume of traffic grew, the wear and tear on the highways became more apparent, and better and stronger materials were required to maintain them.

During the two decades (1920 to 1940), however, rapid expansion of improved highways occurred, and the perfecting of the motor-vehicle equipment has given rise to a substantial volume of commercial operations on the highways. The competition therein afforded by highway transport has been the cause of grave concern, particularly to the railroads, and it has seriously affected their revenues.

In 1921 the highway mileage of the United States aggregated 2,924,505, of which 202,915 miles, or 6.9%, were under the control of the state authorities. The total mileage increased to 3,009,066 in 1930, of which 324,496 miles, or 10.8%, were under the jurisdiction of state authorities. Only 84,372 miles, or 41.6%, of the state-controlled mileage in 1921 were surfaced, and, of this mileage, only 14,707 miles, or 17.4%, were of the high-type surface.

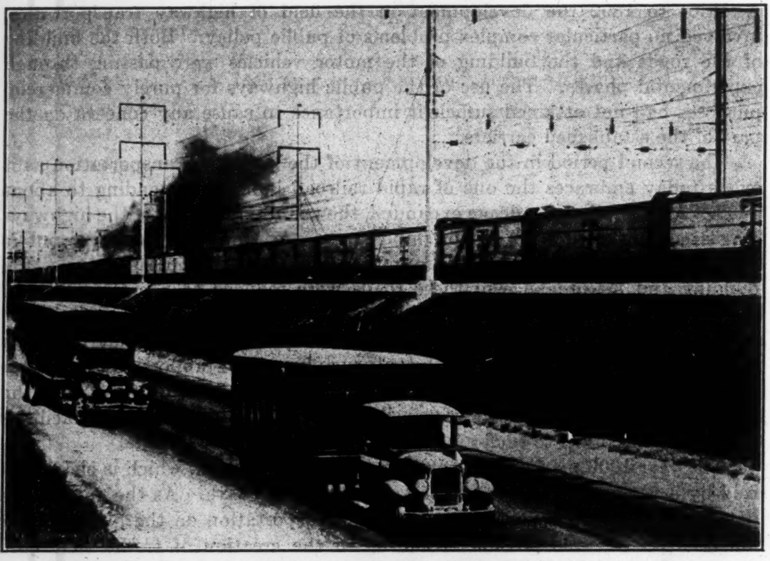

Fig. 3.—The Competition Afforded by Highway Transport Has Been the Cause of Grave Concern to the Railroads

By the close of 1931, significant shifts had occurred in this distribution. The rural highway mileage had expanded only 110,388 miles, or 3.8%, whereas the state highway system had added 126,027 miles, an increase of 62.1%. About 12% of this increase in state mileage was caused by the transfer of local mileage to state systems, rather than by an expansion of the entire road mileage. It is also significant that by the end of 1931 about 74% of the state highway system mileage was surfaced, as contrasted with 42% in 1921. More than 33% of the mileage in 1931 had high-type surface, as compared with 17% in 1921.

During 1931 and subsequent years, various state highway commissions have taken over the supervision of the construction and maintenance of certain county highways which, together with some road mileage previously reported, formed a secondary system of state highways; and at the close of 1938 the existing mileage of public roads and streets under state control aggregated 541,841 miles, distributed as follows:

United States highway system (1938)	Miles
Primary state highway system	326,852
Secondary state highways and county roads under state control	194,428
Total	521,280
Urban expansion of state highways	23,804
Total mileage under state control	541,841

Of this mileage, 424,791 miles, or 78%, have been surfaced. From the foregoing data it may be seen that the state-controlled mileage increased from 202,915 in 1921 to 328,942 miles in 1931, or 62%, and to 541,841 miles in 1938, or 65% over 1931, and 167% over 1921.

Estimates[2] indicate the total cost of the highway system at the close of 1939, including state highways, county roads, and city streets, to be $35,218,000,000, divided as shown in Table 2.

TABLE 2.—HIGHWAY COSTS (MILLION DOLLARS); 1939

Item	Period	State highways	County highways	City streets
1	Prior to 1921	741	4,276	1,921
2	1921 to 1932[a]	4,008	4,720	5,210
3	1933 to 1937[a]	3,933	3,042	3,269
4	1938 to 1939[a]	1,573	1,216	1,308
	Totals	10,255	13,254	11,708
		Grand total		35,217

[a] Inclusive.

The Bureau of Statistics, Interstate Commerce Commission, placed the investment in highways and vehicles used in intercity transportation in the United States at $24,232,000,000, as of 1937. Approximately $12,187,312,000 has been collected from the users of streets and highways through gasoline taxes, the amount for 1939 being $821,656,000 net.

The first automobile appeared in 1892, and from that time the growth of automotive transportation and the development of the extensive highway system in the United States are coincident and interdependent. The record indicates that in 1895 there were four registered motor vehicles. This number increased to 8,000 in 1900, and to 55,000 in 1904. Of these 55,000 vehicles, 410 were classified as trucks and road tractors. From this date, the number of automobiles classified as passenger cars, taxis, buses, trucks, and road tractors increased annually to a total of 9,231,941 in 1920, divided thus: 8,225,859 passenger vehicles and 1,006,082 trucks.

A peak of all motor-vehicle registrations was reached in 1930, when a total of 26,545,281 vehicles was recorded, of which 86.9% were passenger vehicles and 13.1% were trucks. During the next few depression years, the number of registrations decreased, and totaled 23,827,290 in 1933. The number in 1940 was 32,452,861, of which 27,434,979 were privately owned passenger vehicles, 4,590,386 were trucks, and 427,496 were publicly owned vehicles. The percentage of motor trucks had increased from 1.7 in 1904 to 14.2 in 1940.

---

[2] "What Is Public Aid to Transportation?" produced and distributed by the Assn. of Am. Railroads. Estimates for periods up to 1937, inclusive, by C. B. Breed, Clifford Older, and W. S. Downs, Cons. Engrs. Estimates for 1938 and 1939 based on previous 5-yr period.

Passenger-car traffic is fairly homogeneous as to both character of traffic and type of equipment; no such uniformity, however, exists in truck operations. Widely different types of vehicles are used in the several kinds of truck operations, and variations in ownership and operation exist and various types of services are rendered.

The number of trucks engaged in short commercial or private hauling over the highways is not accurately known. It has been estimated, however, that, of the 4,590,000 privately owned motor and tractor trucks, approximately 1,307,000 are farm owned, 2,626,000 are privately owned and not operated for hire, and of the remaining, approximately 262,000 are common carriers and 395,000 are contract carriers. Approximately 86% of all the trucks are operated by the owners, and about 14% are common and contract carriers, operated for hire, or under hauling agreements.

TABLE 3.—MOTOR-VEHICLE STATISTICS; 1940, 1939, 1938.

No.	Description	1940	1939	1938
	(a) INCOME (THOUSANDS OF DOLLARS)			
1	State gasoline tax collections—net[a]	$870,692	$822,013	$772,060
2	Registration fees for all vehicles	373,771	353,533	340,061
3	Fees for permits, certificates of title, fines and penalties	65,407	58,961	48,764
4	Total, items 1 to 3[b]	$1,309,870	$1,234,507	$1,160,885
	(b) NUMBER OF MOTOR VEHICLES REGISTERED, AND GASOLINE CONSUMED (THOUSANDS)			
	Number of Motor Vehicles Registered:[c]			
5	Private and commercial vehicles	32,026	30,615	29,486
6	Owned by federal government	143	121	110
7	Owned by state, county, and municipal governments	284	274	257
8	Total	32,453	31,010	29,853
9	Gasoline consumed (gallons)	21,913,000	20,638,000	19,507,000
	(c) UNITS			
10	Average gasoline tax (cents) per gallon[d]	3.97	3.98	3.96
11	Average persons per vehicle in the United States[e]	4.1	4.3	4.4
12	Average car registration fee in the United States[f]	$11.67	$11.55	$11.53

[a] Plus inspection fees, dealers' license fees, fines and penalties, and aviation gasoline.
[b] Motor-vehicle users in all states paid some or all of the taxes and fees included under items 1 to 3.
[c] Includes trucks: 4,590,386 in 1940, 4,320,829 in 1939, and 4,224,031 in 1938 (see Table 4).
[d] Item 1 divided by item 9. Rates for individual states range from 2¢ to 7¢ per gal.
[e] Population divided by item 5. 10.4 persons in 1921.
[f] Item 2 divided by item 5.

Truck operations have been adapted to a wide range of transportation tasks, which vary from the handling of light farm produce and transportation of household goods, merchandise, and machinery, to the heavy services of logging camps and construction work. The distances over which these operations occur vary widely. Common carriers and contract trucking operations are scheduled in runs of from 50 to 100 miles to more than 1,500 miles.

Small-scale operations and individual managements were characteristic features of commercial trucking operations until about 1930. Since that time there has been a tendency to consolidate trucking operations throughout the country.

Under provision of Act of Congress dated August 9, 1935, the common-carrier truck operators and contract operators handling interstate commerce are subject to the jurisdiction of the Interstate Commerce Commission, and for the period closing with March, 1940, the Commission received reports of revenues, expenses, and statistics representing 1,106 motor carriers of property.

Table 3 shows motor-vehicle statistics for 1938, 1939, and 1940, compiled annually by Federal Works Agency, Public Roads Administration. Registered motor trucks by capacity groups as of December 31, 1939, were as shown in Table 4.

TABLE 4.—REGISTERED MOTOR TRUCKS AS OF DECEMBER 31, 1939

Capacity (Tons)		No.	%
From	To[a]		
....	>1.0	1,641,166	38.18
1.0	1.5	84,974	1.98
1.5	2.0	2,247,219	52.27
2.0	2.5	132,935	3.09
2.5	3.5	108,490	2.52
3.5	5.0	44,138	1.03
<5.0	....	40,078	0.93
Total............		4,299,000	100.00

[a] To, but not including.

Information is not readily available covering the financial status of the various trucking concerns, except through the reports to the Interstate Commerce Commission, which show that for 1939 a total of 1,105 carriers were reported as receiving gross operating revenues aggregating $425,373,099, and operating revenues of $20,663,530, divided thus: 82.5% by common carriers and 17.5% by contract carriers.

For the same year (1939), 196 motor carriers of passengers reported revenue aggregating $143,108,224, of which $123,899,080 was for passengers carried between cities and $19,209,144 was received from local or suburban passengers. The net revenue reported amounted to $20,249,003.

OIL AND GASOLINE PIPE LINES

Pipe lines serve the oil industry by: (1) Assembling crude oil at central points for storage or shipment to refineries; (2) shipments of crude oil to refineries or marine shipping terminals by trunk lines; and (3) long-distance shipment of the principal refined products from field or tidewater refineries or tank terminals. Pipe lines are classified as gathering and trunk lines. The gathering lines are usually laid on top of the ground, and range in size to about 4 in. in diameter, whereas the trunk lines are laid underground, below freezing, and are commonly 6 in. to 8 in. or more in diameter.

The pipe-line mileage of companies reporting to the Interstate Commerce Commission is equal to about 42% of the railway main-track mileage, and amounted to 98,661 miles in 1939, divided thus: 59,108 miles in trunk lines and 39,573 miles in gathering lines.

The development of pipe lines marched side by side with the development of the oil industry. The first successful line, 4 miles long, began operation in the oil fields of western Pennsylvania, in December, 1865, and, 10 years later, a 4-in. line, 60 miles long, was laid to Pittsburgh, Pa. In 1892, there were about 3,000 miles of pipe lines in service, mostly 6 in. in diameter. These connected the oil fields of western Pennsylvania with the refineries in the Eastern States. About 96% of the oil produced prior to 1900 was from fields east of the Mississippi River. During the next 30 years this relationship changed and, by 1930, 66% of the oil came from west of the Mississippi River. In that year the states of California, Arkansas, Oklahoma, and Texas, together, produced more than 86% of all the crude oil in the United States.

Between 1892 and 1914 there was great expansion in pipe-line construction, and at the end of that period five major companies operating in the mid-continent field had a total of 6,059 miles of trunk lines and 3,956 miles of gathering lines. This expansion extended into California, and five companies operating there had lines aggregating 2,439 miles in 1919.

Since 1920 the development has been part of the growth of large oil companies. The numerous oil discoveries in the two decades 1920 to 1940 have resulted in adequate oil reserves and the growth of industry in its many phases; the automotive uses for oil and its products, especially, has increased greatly the demands on the oil industry.

Until 1930, pipe lines were used mostly for transporting crude oil to refineries, and refined oil and gasoline to shipping terminals; since that time they also have been utilized in transporting gasoline from the refineries and shipping terminals to market centers. This practice now exists along the eastern seaboard and from mid-continent fields to Lake Michigan and to Ohio, upper Mississippi, and Missouri river valley points.

The transportation of oil and oil products through pipe lines has become a major industry in itself. In 1921, there was a total of 55,260 miles of gathering and trunk pipe lines operated by companies reporting to the Interstate Commerce Commission. This mileage gradually increased to 98,681 miles in 1939. During the same period, the investment in the industry increased from $365,000,000 to $829,646,000 whereas the operating revenue increased from $115,900,000 to $212,466,000. For 1939, the operating expenses were $97,130,000 and taxes were $31,936,000, leaving a net of $83,401,000. (Fig. 4 shows several hundred of the 20,000 surplus tank cars used in 1941 to alleviate the oil shortage on the East Coast due to the National Defense situation.)

The interstate pipe lines became common carriers and were placed under the jurisdiction of the Interstate Commerce Commission under the Hepburn Act of June 29, 1906, since which time the authority of the Commission has extended over this industry.

The extent to which pipe-line companies compete with the railroads and inland waterway carriers is of considerable interest. Data are not readily available as to the volume of oil products now being shipped by common and contract carriers over the inland waterway routes; however, statistics compiled by the Director of the Bureau of Statistics, Interstate Commerce Commission, and published in February, 1939, show that the railway revenue from transportation of crude petroleum and petroleum products decreased from

$287,027,000 in 1928 to $187,977,000 in 1937, whereas pipe-line revenues increased from $206,438,000 in 1928 to $240,362,000 in 1937.

It is obvious that pipe-line competition has been seriously felt by the railroads. In the past it has not been possible to compare relative cost of pipe-line transportation with railroad transportation. It is the general opinion of railway cost engineers that it is impossible to determine the exact cost of rail transportation for handling oil traffic. However, it appears that, as compared with railroads, the cost of pipe-line operations is relatively low, because of the comparatively small number of employees required. On the other hand, the pipe lines are the only form of transportation other than the railways that do not now receive annual subsidies from the government. The pipe lines never received land grants.

FIG. 4.—THE TRANSPORTATION OF OIL HAS BECOME A MAJOR INDUSTRY

AIR TRANSPORT

Aviation with heavier-than-air machines was born on the sand dunes at Kitty Hawk, N. C., on December 17, 1903, when Wilbur and Orville Wright succeeded in flying a machine equipped with planes and a small gasoline motor for a distance of 260 yd. The Wright Brothers continued their experiments, and on October 5, 1905, at Dayton, Ohio, they succeeded in making their heavier-than-air machine, powered with a gasoline motor, fly a distance of 24 miles, at a speed of 38 miles per hr. During the next 10 years many experiments were conducted in this field, and at the beginnning of the first World War belligerent nations found a practical use for flying. This period (1914 to 1917) provided a powerful stimulus to all branches of flying, and great improvements were made in technical equipment. Intensive development during this period led to constant changes not only in the practice but in the application of flying, so that, when peace came, it was expected that progress would be as rapid as in wartime. The expected progress, however, did not seem to materialize immediately, for at the beginning of 1926 many war experiences had not been fully digested, nor their lessons properly formulated.

The Aeronautics Branch of the U. S. Department of Commerce was established in 1926, and efforts were made to provide airways and aids to air navigation. The first domestic contract air-mail routes were established in that year. Since 1926, this industry has taken the best of skill and methods from older industries, and at the same time it has developed types of materials, devices, and methods best suited to its own efficiency and requirements. Today, less than four decades from the beginning, no industry is more alive to the possibility of technical advance.

The development and production of airplanes have made possible an astonishing advance in the field of transportation, which probably has no parallel in the history of any other common carrier. It was in 1929 that scheduled air transport pioneers first began to be operative. Once each day a small single-engine airplane took off from the Newark airport (which had been recently reclaimed from the New Jersey marshes) and made its way toward the Pacific Coast. It carried an occasional passenger and some mail. Today the national air map reveals a great network of air lines, reaching from the Atlantic to the Pacific, and from the Great Lakes to the Gulf of Mexico. These lines normally fly almost twice as many miles as do the combined air lines of Great Britain, France, Germany, Italy, and the Netherlands; they transport more passengers and more mail, and they surpass the air lines of any other nation in comfort, speed, and safety. Within the same brief period of a little more than one decade, the pioneers of air commerce have linked the United States in scheduled air transportation with Hongkong, China, a distance of 8,746 miles across the Pacific Ocean; with Bermuda, 784 miles from New York in the Atlantic Ocean; and with Central and South America, 7,318 miles from Miami, Fla., to Buenos Aires, Argentina. Since July, 1939, the United States has established transatlantic scheduled air transportation with Great Britain, Ireland, France, and Portugal, 3,437 miles. This service, however, has been interrupted in so far as the belligerent nations are concerned. A measure of the progress of aviation is afforded by reference to Table 5, which contains selected statistical information.[3] It shows the progress of civil aeronautics in the United States by calendar years, beginning with 1926.

TABLE 5.—PROGRESS OF AERONAUTICS IN THE UNITED STATES

Year	Total length of airways (miles)	Total Freightage (Lb)		Total Miles Flown		Passengers carried
		Express	Mail	(Revenue)	Passenger	
1929	36,330	257,443	7,772,014	25,141,499	103,747,249[b]	173,405
1940	94,079	14,188,178	32,700,000[a]	119,517,263	1,265,164,059	3,185,278
Increase (%)	159	5,411	321	375	1,119	1,737

Table 6 shows the financial results[4] for all domestic air carriers for the fiscal year 1939 compared with 1935.

Up-to-date information is not readily available as to the private and public investment in the air transport industry. However, the Bureau of Statistics, Interstate Commerce Commission, reports a total investment for airways and aircraft of $171,000,000 in 1937.

TABLE 6.—OPERATING REVENUES AND EXPENSES OF DOMESTIC AIR CARRIERS

No.	Description	1935	1939	Increase (%)
	Operating Revenues:			
1	Other than United States mail.....	$14,128,249	$30,650,695	117
2	United States mail................	8,814,296	16,669,197	89
3	Total........................	$22,942,545	$47,319,892	106
4	Operating expenses................	$26,264,961	$46,326,581	76
5	Profit (P) or Loss (L)..............	$ 3,322,417 (L)	$ 993,311 (P)	...

The government aids airway carriers by: (1) Establishment and maintenance of air navigation facilities, including construction and maintenance of intermediate landing fields, radio broadcasting stations, radio range beacon stations, radio landing beacons and landing fields, and radio lighting facilities; (2) weather services provided by the U. S. Weather Bureau, U. S. Department of Agriculture; and (3) substantial air-mail contracts. It has been estimated that the sum total of all public aids to this transport agency on a cumulative basis to the present time is more than $400,000,000.

INVESTMENT AND TRAFFIC

The foregoing outlines briefly the history of the transportation agencies serving the people of the United States, and demonstrates that there is a large investment in each. It has been impossible to obtain comparable information on the subject, because of the different methods that have been used by the various agencies in accounting for maintenance and investment. However, the total investment in intercity transportation facilities as compiled by the Bureau of Statistics, Interstate Commerce Commission,[5] as of 1937, was $53,215,000,000 as shown in Table 7. This includes steam railways (including express and sleeping car companies), electric railways, highways and vehicles, waterways and equipment, pipe lines, and airways and aircraft.

TABLE 7.—INVESTMENT IN INTERCITY TRANSPORTATION FACILITIES IN THE UNITED STATES (1937)

Facility	Million dollars	Percentage
Steam railways, express, and sleeping car companies..............	23,706	44.6
Electric railways..................	379	0.7
Highways and vehicles..............	24,232	45.5
Waterways and equipment...........	3,782	7.1
Pipe lines..........................	945	1.8
Airways and aircraft................	171	0.3

[5] Report of Bureau of Statistics, Interstate Commerce Commission, submitted to House Committee on Interstate and Foreign Commerce, January 24, 1939; hearings on H. R. Doc. No. 2531, Vol. 1, pp. 24–25.

The volume of traffic, measured by revenue ton-miles and passenger-miles, handled by the various agencies is shown in Tables 8(*a*) and 8(*b*) for 1939 as compared with 1926. The data in these tables were compiled from the report of the "Committee of Six" appointed in 1938 by the President of the United States to study the transportation situation, corrected to date.

Study No. 3951, made by the Bureau of Statistics, Interstate Commerce Commission, showing the fluctuation in carload freight traffic compared with production for 1928 to 1938 inclusive, shows that the ratio of the actual railroad tons handled to the potential railroad tons declined progressively each year, with the exception of 1934, when the percentage was one point up, until only 78.7% of the potential tonnage was handled in 1938, compared with 1928.

TABLE 8.—COMPARISON OF TRAFFIC AND REV

No.	Facility	(*a*) REVENUE TON-MILES				
		1926		1939		Change[a]
		Millions	%	Millions	%	
	(1)	(2)	(3)	(4)	(5)	(6)

2	Electric railways	1,313	0.2	725	0.1	44.8 D
3	Intercity motor carriers	23,530	3.9	46,000	8.5	95.5 I
4	Great Lakes	90,037	15.2	76,312	14.0	15.2 D
5	Other inland waterways	9,543	1.6	19,937	3.7	108.9 I
6	Pipe lines	21,700	3.7	65,015	12.0	199.6 I
7	Airways	....	....	11	....	....
8	Total	593,567	100.0	543,375	100.0	8.5 D

[a] D = decrease and I = increase. [b] Intercity buses. [c] Includes Pullman and express companies estimated estimated for 1926.

The revenue of commercial carriers for 1939 compared with 1926 is shown in Table 8(*c*). From these tables, it will be seen that the economic position of the steam railways has been declining, and that there has been a very substantial increase in the business of the inland water, highway, and air carriers.

The changes in the transportation "picture" are very significant. What have been the causes resulting in the shift of passengers and freight from the railways to the highways, waterways, and airways? In the broad sense, they are entirely economic. Passengers and shippers use the transportation agencies offering the most satisfactory service at the least direct expense to them. The expense factor being equal, the service factor will govern. The real question before the people, therefore, will be to determine whether or not the free laws of economics govern, and, if not, to what extent competing carriers should be controlled by public authority. It will then be up to Congress to find a remedy to correct the evils and protect fairly and equitably the interests of all concerned.

Taxes Paid by Transportation Agencies

In 1939 the railways paid 8.9¢ of each dollar of revenue for taxes. This is an increase of 78% over 1921, and the trend is still upward. In addition, the railways bear the expense of owning, maintaining, and protecting their properties, amounting to 24¢, which sum, plus taxes, makes a total of 33¢ per dollar of revenue.

The pipe lines reporting to the Interstate Commerce Commission for 1939 had similar expenses, aggregating 15¢ for taxes and 23¢ for owning and maintaining their properties, making a total of 38¢ per dollar of revenue, which compares with the 33¢ borne by the railways.

ENUE IN THE UNITED STATES, IN 1926 AND 1939

for 1926. [d] Comparable data for electric railways not available. [e] Waterway operation and motor carriers

Other transport agencies have somewhat lower taxes in relation to their revenue, due principally to the fact that they do not own and maintain the right of ways or roadbed over which they operate and no taxes accrue against them on that account.

All water carriers reporting to the Interstate Commerce Commission for 1939 paid 2.7¢, and carriers on the Mississippi River System paid 2.5¢ per dollar of revenue in taxes.

Motor truck and bus companies reporting to the Interstate Commerce Commission for 1939 show a tax payment of 7.6¢ per dollar of revenue. The taxes paid by motor truck and bus lines include gasoline taxes and license fees, a large portion of which, plus other tax funds, is used for constructing, maintaining, and protecting the highways over which the carriers operate. The government owns, maintains, and protects the waterways and highways for the benefit of the users, free of charge to them and at public expense.

No portion of the taxes paid by the railways and the pipe lines is used by the government for constructing and maintaining railways and pipe lines. These taxes are used for the normal functions of government, including federal, state, county, and various municipalities. Table 9 shows a comparison of the revenue received and taxes paid by carriers reporting to the Interstate Commerce Commission for 1939.

REGULATION OF TRANSPORTATION AGENCIES

Transportation problems (largely economic) growing out of the increased activity of government, in creating and improving facilities for transportation by water, highway, and air, are becoming more complex. The growth of these various transportation agencies has been sketched briefly in this paper. On inland waterways, improved and maintained at government expense, are barges owned and operated by the government, by common-carrier operators, by contract carriers, and by private individuals or companies. On the coastal waterways, connected by canals constructed and operated by the government, are carriers whose operations are conducted under the fostering care of the government. On the public highways, built partly by gasoline taxes, are carriers operating as common carriers and under contract, and also vehicles operated solely for the use and convenience of their owners. The commercial airplane relies upon the landing facilities generally provided by public authority, and depends for its air operations upon facilities generally provided and maintained by the government.

TABLE 9.—REVENUE AND TAXES, 1939

No.	Description	Group A			Group B			Mississippi River system
		Railways	Pipe lines	Total	Highways	Waterways[b]	Total	
1	Revenue	$3,995,004,000	$212,466,000	$4,207,470,000	$568,481,000	$110,551,000	$679,032,000	$11,744,000
2	Taxes	355,678,000	31,936,000	387,614,000	43,298,000	2,931,000	46,229,000	289,000
3	Tax ratio[a]	0.089	0.150	0.092	0.076	0.027	0.068	0.025

[a] Taxes in dollars per dollar of revenue (item 2÷item 1).

[b] All groups of waterways; includes Atlantic and Gulf coasts, Great Lakes, Mississippi River and its tributaries, and Pacific Coast carriers.

One characteristic in common is applicable to all of these agencies of transportation—their capital is mobile. If their operations prove unprofitable, they can readily be shifted to other scenes, or they can go out of business. This does not apply to the railroads, with their permanent ways and structures; nor does it apply to the pipe lines.

Until recently the problem has been further complicated by the inconsistencies of government policies. There is the related problem of adjustments in the relationships of government to a variety of interests among the several types of carriers, and the all-exclusive groups of taxpayers and of consumers whose welfare it is the duty of the government to conserve.

It has been said that the railways are the backbone of the national transportation system, but this does not deny that other forms of transportation are essential, and in fact indispensable, to the national economy and defense. Certain fundamental problems might be stated thus: (1) To define the field in which each form of transport is superior to the other for service, efficiency, and economy; (2) to determine how services of each form operating in its proper sphere should be coordinated with the services of the other; and (3) to define the extent to which government should impose uniform regulations on all forms of transport, and special regulations, peculiar to its character, on any one form. An incidental question is whether government should undertake by regulation to confine each form of transport to its proper economic sphere or, by permitting unrestricted competition, allow each to find the field in which it can survive. Each form of transport has occupied as much of the transportation field as it could under the conditions existing today. Their services are already coordinated to a considerable degree. Government, both federal and state, has imposed regulations to a very great extent, but not equally upon the different forms of transport.

The regulation of transportation has existed in one form or another from the early time when ways were constructed by the aids of collective effort. In the United States it was not until February 4, 1887, that agreement could be reached in Congress upon a measure that purported to "regulate commerce." In effect, this first act was little more than a declaration of the intention to enter the field of railroad regulation. It created the Interstate Commerce Commission as an agency of enforcement. Since this humble beginning, the authority and powers of the Interstate Commerce Commission have been expanded gradually, until now they are very broad and affect, in varying degrees, the regulation of all forms of transportation, except airways. It was known as the Interstate Commerce Act, and it has been amended many times. Without commenting upon the changes and amendments that have been made in connection with the legislation regulating commerce, perhaps one of the most important is the Transportation Act, approved September 18, 1940. Certain provisions of this Act bear specifically on the problems affecting all transport agencies, and are of vital importance to the national economy. Quoting Title I, Section 1, under the heading, "National Transportation Policy":

> "It is hereby declared to be the national transportation policy of the Congress to provide for fair and impartial regulation of all modes of transportation subject to the provisions of this Act, so administered as to recognize and preserve the inherent advantages of each; to promote safe, adequate, economical, and efficient service and foster sound economic conditions in transportation and among the several carriers; to encourage the establishment and maintenance of reasonable charges for transportation services, without unjust discriminations, undue preferences or advantages, or unfair or destructive competitive practices; to cooperate with the several States and the duly authorized officials thereof; and to encourage fair wages and equitable working conditions;—all to the end of developing, coordinating, and preserving a national transportation system by water, highway, and rail, as well as other means, adequate to meet the needs of the commerce of the United States, of the Postal Service, and of the national defense. All of the provisions of this Act shall be administered and enforced with a view to carrying out the above declaration of policy."

This is the first time the Congress has recognized the necessity of dealing with the various transportation agencies collectively, instead of separately.

There has been no comprehensive view or proper consideration of the interrelation between the various agencies of transportation that are now competing for the same traffic throughout the United States.

For the first time in American history, subject to the provisions of the Act, the Congress is requesting a fair and impartial regulation of all agencies of transportation. The writer mentions this because airways are definitely omitted from the Act. The airways are kept separate from the others. This is a mistake because it is impossible to deal fairly with a single transportation agency without a broader view.

Another provision, under Title III, Section 301, relates to the establishment of a Board of Investigation and Research, to be composed of three persons, who shall be appointed by the President, for the purpose of investigating and reporting upon the following:

> "(1) The relative economy and fitness of carriers by railroad, motor carriers, and water carriers for transportation service, or any particular classes or descriptions thereof, with the view of determining the service for which each type of carrier is especially fitted or unfitted; the methods by which each type can and should be developed so that there may be provided a national transportation system adequate to meet the needs of the commerce of the United States, of the Postal Service, and of the national defense;
>
> "(2) The extent to which right-of-way or other transportation facilities and special services have been or are provided from public funds for the use, within the territorial limits of the continental United States, of each of the three types of carriers without adequate compensation, direct or indirect, therefor, and the extent to which such carriers have been or are aided by donations of public property, payments from public funds in excess of adequate compensation for services rendered in return therefor, or extensions of Government credit; and
>
> "(3) The extent to which taxes are imposed upon such carriers by the United States, and the several States, and by other agencies of government, including county, municipal, district, and local agencies."

The national transportation policy and the provisions of the Act to make such a study as outlined are definitely related. The policy is to be "so administered as to recognize and preserve the inherent advantages of each." What is meant by "inherent advantages"? Would not the words "relative usefulness" be more appropriate? The ability to serve all of the transportation needs of the Nation in all seasons and under all conditions should be an important consideration. The President's Board should be very helpful in determining this policy.

Pipe-line transportation is the only one that is highly specialized in the United States and, of course, no one claims that it is capable of supplanting other agencies for full community needs. It is hoped that in administering the policy, a "yardstick" will be applied that will recognize these facts.

The national policy is to promote "safe, adequate, economical, and efficient service and foster sound economic conditions in transportation and among the several carriers." The terms "safe, adequate, economical, and efficient" require no comment. However, the meaning of "sound economic conditions" may be vague when applied to the several transportation agencies. Is it the intent of the Congress that all agencies of commercial transportation should be self-supporting, or does "sound economic conditions" imply a continued government aid to some forms of transportation?

It would appear that, under Title III, Section 301, of the Act, the President's Board will be expected to weigh all of the factors affecting the economies of the railway, highway, and waterway carriers; it will consider all costs of transportation—those borne by the shippers and those borne by the taxpayers.

The national transportation policy is "to encourage the establishment and maintenance of reasonable charges for transportation services, without unjust discriminations, undue preferences or advantages, or unfair or destructive competitive practices." If fair and impartial application is made of these principles, many of the important factors that are effecting chaos will be eliminated.

The declaration, "all to the end of developing, coordinating, and preserving a national transportation system by water, highway, and rail, as well as other means, adequate to meet the needs of the commerce of the United States, of the Postal Service, and of the national defense" is of interest. It is the opinion of many that there are too many transportation facilities. The national transportation burden is now at its height, for that reason. The three agencies mentioned are more than adequate to meet the needs of commerce, and the government continues to develop more facilities by water, highway, and air. What about national defense? The railway is indispensable, as has been testified by competent Army officers. If additional facilities are necessary for this purpose, a much greater capacity can be developed for the least expenditure, in rail facilities, as compared with waterway and highway expenditures. The Army engineers in charge of waterway investments, from the beginning, have given little consideration, if any, to existing facilities, when contemplating the extension of waterway facilities. The economic justification rests upon diverting traffic from existing facilities to the waterways. Coordination cannot come out of such a policy. No doubt the President's Board will weigh very carefully all of the many controversial factors affecting this problem.

TRANSPORTATION COSTS

This paper will not be complete without a brief discussion of transportation costs as may be considered by the President's Board of Investigation and Research. Among other things, it will be authorized to ascertain, if possible, "The relative economy and fitness of carriers by railroad, motor carriers, and water carriers for transportation service, or any particular classes or descriptions thereof, with the view of determining the service for which each type of carrier is especially fitted or unfitted." One of the most important factors to be considered by the Board will be the actual cost of producing transportation by these types of carriers. This will be most difficult, if not impossible, to accomplish. Railway cost engineers and the Statistical Division of the Interstate Commerce

Commission have had this question before them for many years, as it applies to the railroads, and in recent years to the highways, and up to now (1941) the results have not been comforting. There may be more than one method of approach to this problem. The one that has been so complex and difficult is to determine what it costs to transport persons and property (classified as to commodities) by the various transport agencies without regard to the amounts paid by the users. This method meets with very serious handicaps, because of the impossibility of determining the costs as applied to individual persons and various kinds of property. This would be particularly ~~true in~~ connection with railway, waterway, highway, and airway transportation. Oil and gasoline constitute the major part of property transported in pipe lines in a fluid form, which, of course, simplifies the problem of cost finding. With the railways, waterways, highways, and airways, all of which transport many classes of commodities, the problem has not been solved. It naturally follows that, if this method of approach is used, it will be necessary to determine costs applicable to passenger, mail, and express; costs of l. c. l. (less than carload-lots) packages of all sizes and weights, and freight of all kinds moving in carloads, for long hauls and for short hauls (all mixed up in long trains and short trains, in large or small motor vehicles, steamboats and barge tows, and air transports) and for varying operating conditions as may obtain throughout the United States.

All transportation agencies are competing for business by means of a pricing system and service offering that have resulted in dividing the potential traffic among the various agencies. Records are available of the revenues and expenses of all common carriers reporting to public authority. The differential between the total revenues and total expenses of the carriers is so narrow that the price paid by the shipper might properly be considered as the cost of transportation.

The amount of government aid, particularly in connection with the highway carriers, is not easy to determine. A number of studies have already been made for the purpose of finding out if the commercial users of the highways are paying their full share. The highway carriers claim that the various tax levies plus gasoline taxes more than compensate for the use of the highways. The railroads do not agree. When the total of public aid contributions is added to the total amount of the carriers' expenses, or the total amount paid the carriers by the shippers, it should not be difficult to determine the relative total economy of the various types of transport agencies.

With accurate data as to the amount of government aid affecting transportation, it would then become a matter of public policy as to whether or not such aid should be continued or withdrawn. If all forms of government aid were withdrawn from commercial transportation agencies, economic laws would soon point out which form of transportation was the most economical and satisfactory to the users. The elimination of government aids, except for experimental, promotional, and defense purposes, would solve the problem now so vitally affecting national transportation. Therefore, it seems logical that the first thing the President's Board should do is to develop, very carefully, the amounts of government aid now reflected in the cost of commercial transportation in all of its forms. Much has been accomplished already in this respect.

Joseph B. Eastman, when federal coordinator, evidently had in mind the importance of the question of subsidy, or government aid, to the various transportation agencies when he undertook to prepare the four large volumes of "Public Aids to Transportation," which were begun, through his Research Section, in 1933–1936, and later completed and issued by the chairman of the Interstate Commerce Commission in 1940. This report contains a great wealth of valuable information, together with comments and conclusions.

In October, 1940, J. J. Pelley, President of the Association of American Railroads, released a reply entitled "What Is Public Aid to Transportation?" (produced and distributed by the Association of American Railroads), which is an analysis of the data contained in Mr. Eastman's report, and points to inconsistencies that render the conclusions incomparable, confusing, and misleading.

Here are the results of two studies that have a direct bearing on the future work of the President's Board of Investigation and Research, and it will be well for all who are interested to study in great detail the information contained in both of these reports.

ACKNOWLEDGMENTS

Credit is due the Association of American Railroads; Brookings Institute ("The American Transportation Problem"); Federal Works Agency, Public Roads Administration; Interstate Commerce Commission; Office of Chief of Engineers, U.S. Army; U. S. Department of Commerce, Civil Aeronautics Administration; and others for information contained in this paper. Fig. 1 was supplied by the Southern Pacific Railway Company, and Fig. 4 by the Pennsylvania Railroad Company.

DISCUSSION

Fred Lavis,[6] **M. Am. Soc. C. E.**—The author merits the thanks of all those interested in problems of transportation for having presented such a comprehensive and statistically well-fortified review of transportation developments during the last century, as well as a broad picture of the internal transportation system of the United States as it now exists.

Too many people have only a narrow and meager comprehension of the entire problem which, as the author states in the "Synopsis," is one "so vital and so far-reaching that a sound national economy may depend on its solution."

The author has painted a fair and unbiased picture of the entire situation. He only alludes very briefly, however, to the vast number and great importance of the many indeterminate factors that prevent any reasonably accurate determination of relative costs of transportation by most of the facilities in use today.

What is the value of the property used by the railways? How can such value be determined? What are the costs of highways—original cost, reconstruction, and maintenance? How are the costs of providing and maintaining highways to be distributed among, through long-distance traffic, local freight traffic, and ordinary automobiles used for business, for pleasure, and for access to property?

What are the effects of curvature, varying rates of gradient, rise and fall, distance, smoothness and width of pavement, separation of lanes of traffic, separation of cross traffic, etc? Should drivers of motor vehicles who benefit by improvements pay a special tax for them?

What part of highway costs may be chargeable to military use?

How do railways or highways or even waterways affect the values of adjacent, or more or less near-by, properties? To whom do accretions of value belong? For instance, on a highway like Route 25 in New Jersey through Jersey City, Newark, and Elizabeth, how much of its cost or value should be allocated to traffic between the remainder of the United States and New York, and how much to the State of New Jersey? How much are the cities through which it passes benefited by having this traffic taken off their streets?

What proportion of the costs of the Westchester parkways should be borne by the county, the state, and the City of New York? Should the traffic which uses these parkways, and thereby saves time, tires, and gasoline, pay a proportionate part of their cost? A large book could be written about these and other questions and difficulties of determining costs of transportation.

The associations of highway builders and users have proved to their own satisfaction that all highway costs are covered by taxes paid by their users. The railways have proved equally conclusively (or with equal ignorance) that this is not so. The truth is that neither knows.

Table 7, as given in the paper, might easily be misinterpreted either because of lack of thought or wilfully. There, it is shown that about 90% of the total investment in intercity transportation facilities in the United States is for railways and highways, being divided about equally between the two. The point to be noted, however, is that the railway plant is purely a transportation machine whereas the highways are in a fairly large degree ways of access to lands and, in not a few instances, adjuncts of recreation.

---

[6] Cons. Engr., New York, N. Y.

It should be emphasized also that railways perform a service in moving bulk freight and large numbers of passengers that cannot be moved by any other known means of transportation, and one without which the United States could not exist as a nation even in times of peace. For war, of course, their value is inestimable.

The author points out one step that may be taken—namely, the determination, with some approach to accuracy, of the amount of government aid affecting the provision of transport facilities and costs of transportation. That very likely may be of value.

He suggests (see heading "Transportation Costs") that "If all forms of government aid were withdrawn from commercial transportation agencies, economic laws would soon point out which form of transportation was the most economical and satisfactory to the users." In theory this is right. In practice it is not possible.

Water transportation is mixed up with flood control. Air transport has been a development of incalculable benefit to the United States and to the world, if it is conceded that the world, and transportation in the world, must advance. The construction of highways is strictly a governmental function—national, state, county, and municipal. Highways must be built with public funds.

There remain the railways, ground between the millstones of demands of organized labor for higher wages, regulation of rates by the government and, at least to some extent, competition of subsidized highway and water transportation.

The President's Board may be able to arrive at a fair determination of costs by the various different forms of transportation but this is doubtful.

The war has shown, and will show more conclusively, the absolute need of both railways and highways in the United States. The highways will be taken care of. The users, and that means the public generally, will see to that. The railways are a different problem.

It is the suggestion of the writer that the President's Board concentrate on a problem which can be solved—the maintenance in the United States, not of a governmentally owned railway system but, of a railway system that will provide efficient service at the lowest cost consistent with financial integrity.

WILLIAM J. WILGUS,[7] HON. M. AM. SOC. C. E.—This timely and informative paper on the Nation's transportation problem comes to fill a need that has never before been so pressing. The array of pertinent facts and data is impressive. To them, however, it would seem well to add others essential to the making of a sound diagnosis, as does the physician in searching for all the symptoms of a bodily ailment before announcing its causes and the measures, though painful, then to be taken for its cure. The age-old Delphic admonition, know thyself, is to be heeded in this if genuine success is to attend the effort.

---

[7] Weathersfield, Ascutney, Vt.

The physical and financial aspects of the problem are not alone to be considered. There is also a psychological aspect that plays an enormous part in the interplay of forces bearing on the movement of persons and property from place to place. Man, by his very nature, prefers to do things for himself when thereby he may gain convenience, time, pleasure, and independence, as in the use of the motorcar. Then, too, there is his inborn urge to escape from what he deems to be the exactions of corporations dominated by unconscionable "high finance," so recently revealed at Washington.[8] Again there is his feeling that his products often may be moved to markets by highway and waterway at rates he can afford to pay, when they would remain immobile were there no such escape from shipment by rail at higher rates. In this attitude he is ignoring the countervailing fact that he must look to the railroad for never-failing service when its competitors are locked in ice and snow. Then he shrinks both from the subsidizing of tax-burdened railroads, controlled as they are by the "high finance" he fears, and the withdrawal of aids to their rivals with resulting higher rates to be borne by him, even though he recognizes the unfairness of favoring one and not the other. Finally, there is his conviction that, were it not for competition offered him by highway, waterway, airway, and pipe line, he would be powerless to secure by rail the rates and service he now enjoys, or is striving to obtain. The argument that through taxation he is paying, indirectly, additional sums for these advantages is to him an abstraction that "leaves him cold," as does the other argument, well founded though it is, that the increasing diversion of his traffic from the railroads to their subsidized competitors will in the end land the railroads, exhausted, in his lap. These are human attitudes that cannot be "poohpoohed." They have had a tremendous effect on the development of transportation and will so continue. They are among the causes that must be given weight.

From the physical and financial angle the situation is no less difficult. The railroads—backbone of the Nation's transportation—are looked upon statistically as a national system, as they are in a physical sense. In this view the public is prone to be led astray. Though interconnected, with traffic flowing over them uninterruptedly to and from all parts of the United States, they are in truth separately owned and controlled by a multitude of corporations having diverse interests and varying in their financial status from the wofully weak to the excessively strong. Collective statistics for all of them are not applicable individually to their widely differing members. Their lack of managerial unity may be compared with the original thirteen states before they were federalized in 1789. They are without a compelling head to direct their efforts impartially for the common good—all for one and one for all—the strong to assist the weak, each being equally necessary for the public good. In the absence of unity their development as a whole has been checked, while their rivals are advancing. Highways are being extended and improved on a vast scale; waterways, often unworthy products of the malodorous "pork barrel," are "on the march"; and airways are in the picture with promise of great things to come. As to pipe lines, sight should not be lost of those devoted to the movement of natural gas and powdered substances in fluid suspension, as well as oil and gasoline mentioned by the author; nor should the effect of electric transmission lines on the movement of rail-borne coal be ignored.

---

[8] Senate Rept. No. 25, 76th Cong., 1st and 3d Sessions, Pts. 1 to 27, inclusive, and Senate Rept. No. 26, 77th Cong., 1st Session, Pts. 1 and 2.

In considering the development of transportation affecting the redistribution and relocation of industry, internal and foreign trade, and the Nation's safety in time of war, all of these interrelated means of movement—railroads, highways, waterways, airways, pipe lines, and transmission lines—should, of course, be given heed. The railroads, in particular, should be given consideration in their straightened circumstances.

A glance at the development of Class I railroads will disclose that their property investment from 1916 to 1940 (each of these years preceding the entry of the United States into war) increased from 17.6 billion dollars to 26.3 billion dollars, or nearly 50%, and the stockholders' equity in the hands of the public, in excess of the funded debt, from, say, 8 billion dollars to 16 billion dollars, or 100%. Corresponding to this, net income available for dividends and surplus decreased from 647 million dollars to 189 million dollars, or 71%, while cash actually disbursed in the form of dividends to stockholders with which to buy their bread and butter decreased from 306 million dollars, or 4.4%, to 159 million dollars, or 2%. On their equity, including the additional 8 billion dollars of "venture capital" which they had "plowed back" and otherwise put into their properties, their dividends dropped from something like 4% to a little more than 1%. Even these meager dividends were not earned in the 9 years from 1931 to 1939, inclusive, during which the deficits thus incurred aggregated something like a billion dollars.

The results of this unhappy picture are reflected in the money market where the railroads' aggregate property investment in excess of 26 billion dollars, represented by a net capitalization outstanding in the hands of the public totaling 17.6 billion dollars, has a quoted value of the order of, say, 10 billion dollars. In the face of this decay in values it is easy to understand why pre-depression gross capital expenditures on Class I railroads, averaging upwards of 800 million dollars per annum, dropped to an annual average of 276 million dollars during the 10-yr period from 1931 to 1940, inclusive. The plant as a whole, therefore, could not hold its own in a sharply competitive field in which a billion dollars of new railroad investment annually, according to competent authority, was deemed necessary for that purpose. Between 1916 and 1940 total railway line mileage has retreated from 254,037 to 233,670. In the service of Class I railways, locomotives have decreased in number from 61,332 to 41,721, although their tractive effort has remained the same; freight cars from 2,253,233 to 1,653,663, and in tons capacity from 92,280,335 to 82,722,361; and passenger cars from 52,179 to 37,817. From 1930 to 1940 maintenance was neglected, perforce, and modernizing was put aside—other than on what may be termed the luxury routes. The much more extensive mileage of lesser main lines and branches patronized by an inarticulate public has borne the brunt of deprivation.

Despite competent management as manifested by a remarkable growth in the efficiency of operation, the development of railroad transportation therefore has not been upward; nor are the results of the present war-time boom to be taken as the mark of a permanent change for the better. In the words of Ernest E. Norris, president of the Southern Railway Company:[9]

> "We can foresee the thin trickle of traffic that will flow from post-war readjustment. We can divine the savage competition that the railroads will face for every ton of that traffic. And, without stretching our imagination very far, we can visualize the devastating effects of these two certainties. We can see revenues declining; expenses frozen; profit a dimming memory; capital stoutly—and rightly—refusing to invest in an industry faced with government-nursed competition."

In this it should not be forgotten that, although the owner has received a constantly lessening return on his vastly enlarged investment, the other interests involved (managements, including the interests that control them; labor; shippers; and the general public) have had increasing rewards. As has been said by an authority in the railroad field:[10]

> "Railway management cannot truly boast it is really doing a good job as long as only about one-sixth as much net income is being earned for railway stockholders as was earned for them in the decade before the present depression."

As the evidence clearly points to the impossibility of railway management doing the "good job" with no "prince" in sight to rescue its "Cinderella," the conclusion is inescapable that the railroads in their entirety cannot finance the necessities essential to their continuance as a quasi-public enterprise in private hands. In the words of the foregoing authority:[11]

> "If the United States should begin to climb out of the slough of depression and unemployment in which it has so long reposed, large additions to railroad plant and equipment would be needed, and 2 per cent isn't enough earnings to attract adequate capital. The railroads need a new program to supplement their 'ready' theme; and one which will hold out some hope to railway owners. Why should these latter wish to avoid government ownership, if private ownership continues indefinitely to give them nothing."

Now war is here, with the Nation's transportation situation in what may prove to be "a tight corner." The failure of the railroads to obtain materials constitutes "the greatest and most imminent danger that threatens the provision of adequate and efficient railroad service during the remainder of the present emergency." The President's Board of Investigation and Research, referred to by the author, has been injected into an interterritorial rate controversy quite foreign to its purpose.[12] An unhealthy increase in passenger and freight rates is imminent. Demands for trained personnel, materials, and equipment on an enormous scale are in sight for service overseas, in respect of which the United States is totally unprepared.

---

[9] "Railroad Data" from the Eastern Railroad Presidents Conference, November 21, 1941.

[10] Editorial in the *Railway Age*, July 20, 1940.

[11] "The Week at a Glance," *ibid.*

[12] "The Week at a Glance," *ibid.*, January 10, 1942.

The writer, under the circumstances, sees no reason to change the views he expressed in 1939.[13] They point to a way in which, as he believes, the development of railroad transportation may be checked in its dangerous downward course and moved upward as befits the times. The day has gone by for more investigations, further reports, and lengthy studies when Fate is knocking at the door. Action is what is needed, and that quickly. Much responsibility for this action lies in the hands of the newly appointed Director of Defense Transportation.

Joseph B. Eastman,[14] Esq.—Some of the problems treated by Mr. Teal are not quite as simple as they seem. For example, when it comes to determining the relative costs of the different forms of transportation, an over-all picture is afforded by comparing the rates that the public pays and adding something for what one may think is the public aid received; but, after all, the important point is to determine in what particular places each form of transportation can serve best—what particular kinds of hauling they can do better than some other kind of carrier. Now that involves quite a detailed study. There are not many short-cut methods that will yield that answer. It requires a long and very careful study, and the great difficulty is that the picture is changing all the time. It is not static, and that is one of the great difficulties that the President's new Board of Investigation and Research will encounter. That part of the Transportation Act of 1940 was really taken from a bill drawn by the writer in 1938 for the creation of a national transportation authority (Federal Transportation Authority), and at that time he had in mind a permanent agency that would be studying these questions all of the time—not necessarily making big reports on them, but applying pressure here and there, exerting influence, and offering advice where it is thought it would do the most good.

As a purely temporary organization, directed to make a comprehensive study of this question of relative costs, the President's Board will encounter some difficulties before it completes its work. Public aid to transportation is a problem that could be discussed all day and all night. The writer has produced four volumes on that subject. Railroad administrators probably do not disagree with the writer so much when it comes to the water carriers. Probably they do not disagree with him greatly about the air carriers or the railroads. They do disagree most emphatically with respect to the highway carriers, and there are many questions which are not only questions of fact but questions of public policy.

The question of whether it is possible to reduce the number of trackage miles, for example, between Chicago, Ill., and Cincinnati, Ohio, is a very large one. There is no doubt whatever that if the railroad systems were operated as a unit and the traffic were directed over the best routes between the important points, considerable money could be saved. There are some objections to that possibility also. The four lines of railroad between Cincinnati and Chicago do not follow precisely the same routes. There are many places on each of those lines that are not served by the others, and people at those points, of course, would not appreciate it if their service were abandoned.

---

[13] "Nationalization of the Railroads?" by William J. Wilgus, *Civil Engineering*, October, 1939, p. 593.

[14] Director, Office of Defense Transportation, Washington, D. C.

An elaborate study of this problem was made under the so-called "Prince plan," which would combine the railroads into seven systems—two in the East, two in the South, and three in the West—and change the routing of traffic, concentrating it in various ways to obtain large savings. A group of railroad engineers and traffic men investigated that plan for the writer when he was federal coordinator. Whereas authors of the plan put the savings at about $700,000,000, that committee reduced it to something like $250,000,000. There is no doubt whatever that, in connection with any such plan, a large volume of objection would arise from the public in various respects.

For example, such a plan would leave Baltimore, Md., served by one railroad system; New York, on the other hand, would be served by two; and Chicago would be served by at least four, and maybe five or six. That kind of an arrangement would cause considerable objection. People at points located on what would become secondary railway lines under such a plan as that would complain because they were removed from the main arteries of commerce. It is not a problem that can be dealt with simply without considering all the various angles. The writer feels that there are important savings that could be made through consolidation of the railroads, combined with coordination (that is, cooperative effort in places where their interests are in common, such as at terminals), and at the same time preserve and probably improve the service to the public; but as he found when he was federal coordinator, this is a very debatable subject.

J. L. Campbell,[15] M. Am. Soc. C. E.—The paper presented is a valuable historical review of the development of transportation by railways, waterways, highways, airways, and pipe lines in Continental United States.

Between the several kinds of transportation, important issues lie in matters of need and capacity, extensions or enlargements, costs, competition, regulation, and coordination of transportation services. Out of right settlements or adjustments of such issues, unified, adequate, and cooperative transportation would flow at fair costs promoting national prosperity and welfare.

Developments of transportation on the highways and the airways are in a fluid status making probable no early sound and adequate solution of the entire problem which should be assigned to a commission composed of men of best ability and experience for the task. Such solution should be translated into appropriate legislation. Meanwhile, "first aid" is necessary for the preservation of railway transportation, the major part of all transportation. Such aid lies within the discretion of the Interstate Commerce Commission.

In terms of volume, value, and indispensability, railway transportation towers above its competitors. It is the backbone of transportation to which other forms should be adjusted in equitable relations and fair competition so that the backbone shall not be broken or incapacitated in the major service it must render. As between railway transportation on one side and waterway and highway transportation on the other side, regulation and competition have been unfairly adverse to transportation by railway because transportation by waterway and highway has not paid the full cost of its service and has not been subjected to the rigors of railway regulation. Regulation should cover fairly all competitive transportation.

---

[15] Chf. Engr., Northwestern Pac. R. R. (*Retired*), Oakland, Calif.

While the trend of railway revenue rates has been generally downward or *in status quo*, the trend of unit costs of labor and materials used by the railways has been upward. Since 1920, there has been growing diversion of traffic from the railways to the highways. This is reason enough for the present financial condition of the railways wherein about one third of railway mileage is now in receivership and the remainder of it is unable to earn a fair return upon investment except in periods of abnormal traffic of great volume. For normal traffic, railway revenue is generally below railway expense. This result is largely due to too much limitation of railway revenue by fiat of law and dicta of the Interstate Commerce Commission. A railway dividend is now almost a curiosity to be placed under a glass case in the Smithsonian Institution.

In volume, excellence, and relatively low cost of transportation, the American railway system is unequaled anywhere. It has avoided complete shipwreck and has continued operation as a private enterprise under rigorous regulation by improvements and efficiencies in its plant and service which have reduced cost of transportation and partly bridged the gap between revenues and expenses. It is probable that a point would be reached beyond which the cost of additional improvement and efficiency would widen rather than close the gap. It is improbable that inadequacy of revenue can be completely and permanently eliminated so long as revenue rates are frozen and unresponsive to economic conditions. Unless the rates are substantially maintained in such relation to cost of service as will assure a fair return to private initiative and enterprise, the inevitable end will be government ownership and operation. Thereby, the record indicates that cost of transportation would increase.

Commercial traffic on the highways being so directly and highly competitive with railway traffic should be closely coordinated with its competitor and be subject to the laws controlling railway transportation to the end that regulation of railways and highways as commercial transportation agencies shall be common and equitable to both. Multiplicity of transportation agencies on the highways retards rather than expedites traffic thereon. In so far as the public interest and convenience are promoted thereby, commercial highway traffic should be conducted by the railways.

The national system of highways came into being by the simple and relatively inexpensive process of covering the surface of existing wagon roads with some sort of pavement, the alinement of the roads having remarkable similarity to the meanderings of the covered wagons of the heroic days of Westward Ho. The result is a system of paved highways which, in alinement, gradients, widths, and paved surfaces, is distressingly and dangerously inadequate for the volume and speed of today's highway traffic. Only a beginning has been made on necessary nation-wide reconstruction of this system to standards indispensable to highway requirements of today and the future. This is a reconstruction job which, when done, will have cost vastly more than the original paved roads.

Transportation on the Great Lakes being comparable to transportation on the oceans is the most economical transportation within Continental United States. This is not true of the rivers and canals whereon ton-mile cost is more than on the railways. Relative to the railways, rivers and canals are few in number, limited in mileage, non-elastic in location, and incapable of serving more than a small part of the total tonnage of the country. The railways have surplus capacity more than sufficient to carry the tonnage carried on the rivers and canals. All transportation requirements could be served without the rivers and canals. That would be impossible without the railways. In general, vast expenditures for navigation on rivers and canals have been made without economic justification. Such expenditures should cease.

A vital function of river channels is to carry away the flood waters of the continent. The drainage capacity of these channels should not be diminished by navigation structures without weighty reasons therefor. This was brought vividly to mind during the great 1937 flood on the Ohio. There is some conflict between flood control and navigation on rivers.

Waterway transportation should be required to raise its service rates sufficiently to cover total cost of plant and service and yield a fair return on investment so that its competition shall be fair to its competitors who must fix their rates as described. This also applies to airways and pipe lines.

The airways are too young for final conclusions thereon.

W. W. Crosby,[16] M. Am. Soc. C. E.—In this paper the author has set forth, most interestingly, many of the facts regarding the appearance and growth of the various facilities. He states that under present conditions all are competitive and that "unfair competition" has resulted. From purely financial viewpoints many observers would have the same view; but that is not the only aspect that should be considered in attempting corrections of the existing situation.

The development of waterways had a basis of regional interest besides the economic one. The railways had a considerable basis of national interest underlying their economic one—regardless of their prostitution by "high finance." Pipe lines were based almost wholly on financial interest, although a secondary result may have been to advance regional interests. Air transport has developed from a national, if not international, interest. The interest underlying highway development has been almost wholly local or parochial.

Considering these underlying motivations, it becomes apparent that, although some of the much-needed coordination could be had beneficially by cooperation (and possibly by some regulatory action), a more fundamental remedy must be sought. Legislation against the developments of applied science is not the American way to protect the Nation; nor is it even in the financial interest. Cleaner, clearer, and broader thinking than has prevailed is needed for the national welfare as well as for National Defense.

---

[16] Cons. Engr., Coronado, Calif.

All through the warp and woof of highway development have run such threads as "taking the farmer out of the mud," "all-year roads," "farm-to-market highways," "express ways for faster traffic," and "safer and more commodious highways." A very few suggestions of national interest occur. One was indicated perhaps by Congressional provisions for the national roads mentioned by the author. Possibly a second short thread may be found in the "National Highway" movement and others early in the twentieth century. Most of them broke off rather shortly.

The writer believes that careful analysis proves that even these latter were more regional at the bottom than national. The combining of local and regional highway systems to form "national highways" has been more fortuitous than otherwise, and it occurred as an afterthought rather than as an original concept for national benefit. L. I. Hewes,[17] M. Am. Soc. C. E., has stated that "The history of this strategic net [of national or defense highways] goes back to the Federal Highway Act of 1921"; but the earlier results were simply the linking up, for long-distance facility, of existing roads into a "Pershing Map" in 1922. A revision of the Pershing Map was made in 1939, and was thereafter called the "Highway Map Showing Main Traffic Routes of Military Importance." Another revision was made under date of May 15, 1941.

Then Mr. Hewes states that "These main routes are intended to connect all important foci of actual or potential importance for defense. Clearly, the strategic net is used much more by civil than by military traffic." The foregoing quotations seem to the writer to support his statement preceding them.

With the possible exception of the "Harrisburg-Pittsburgh Turnpike," the writer remembers no highway in the United States that has been originated from a conception of the national, or even of a major regional, interest. Italy and Germany did do this many years ago; but the results so far obtained in the Unites States have come merely from piecing together local roads built for local ends and from narrow conceptions of what would gratify local or small regional desires. The federal influence has not been exerted effectively otherwise, and even as late as 1941 federal agencies seem to have continuously disapproved the broader idea.

A further fact in explanation of the insufficiency of present improved highways in National Defense is that the federal road authorities have clung too long to their announced principle that "the improvement of a highway is solely justified by the savings in transportation costs." Another fact may be that state highway authorities too often have been concerned mainly with the influence of highway expenditures on votes. The writer already has emphasized[18] that this criticism is not directed against engineers as such. At times, however, they are forced to share it.

The author states (see heading "Investment and Traffic") that the causes of "The changes in the transportation 'picture'" have been "in the broad sense, * * * entirely economic"—that is, "satisfactory service at the least direct expense." Does he not go too far? The writer thinks that Mr. Eastman (quoted by the author) has showed[19] a more complete understanding when he stated "Competition between different forms of transportation * * * has become essentially a warfare * * *" that "compels attention to the needs and desires, and even the foibles, of the public which is being served."

---

[17] "Better Highways for National Defense," by L. I. Hewes, *Civil Engineering*, January, 1942, p. 10 *et seq.*

[18] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 1115.

As the writer has contended heretofore, too great reliance has been placed in highway matters on mathematical formulas, financial returns (real or figurable), local political influences, and personal ambitions, with not enough reasonable regard for convenience, safety, and national interests. He does not believe that the durable solution of the desired coordination will be found in "transportation costs" alone. If "convenience" is to be considered, it may even be that highway competition with railway facilities will be increased. "Technocracy" has its appeal to the scientific mind; but as such its further reasoning was undermined long ago by the truths of Kipling's "Imperial Rescript."

Coordination is needed today. It is even indispensable. The author mentions this but seems to believe that the "coordination" desired is the subordination of other forms of transportation to the financial benefit of the railways. Neither the history of the railroads nor the developments of transportation science justify such a conclusion, economically or otherwise. The Transportation Act that he quotes seems to the writer to indicate a much broader view; and Mr. Eastman himself seems on the side of the writer.

Recently the writer had the occasion to mention to the National Resources Planning Board an instance of deplorable lack of coordination under his personal observation. The reply, dated September 19, 1941, was that "unfortunately, co-ordinating machinery for an over-all transportation approach (to the local problem) does not now exist in the Federal Government." To the writer's further suggestion that possibly the National Resources Planning Board might obtain the help of the Public Work Reserve Agency described by Melvin E. Scheidt,[20] M. Am. Soc. C. E., in October, 1941, the reply was that the Public Work Reserve Agency was "merely advisory to State and local governments on matters of procedure."

The appointment of a federal coordinator of transportation in the person of Mr. Eastman, Chairman of the Interstate Commerce Commission, lends encouragement to the idea that broad consideration may yet be had of national transportation problems with acceptable coordination of present and future facilities. It is to be hoped that the solutions will not be based entirely on consideration of profits to any of them.

W. B. Irwin,[21] M. Am. Soc. C. E.—A broad and comprehensive presentation of current transportation conditions is contained in this paper.

It has been characteristic of the development of the United States that the more convenient and expeditious mode of transportation supplanted the less efficient. Nothing, however, has been evolved to displace the railways in economy or efficiency for mass transportation of passengers or freight.

The trend of railway transportation is to maintain the highest standard of service warranted by traffic requirements and to abandon obsolete lines as rapidly as the requisite authority can be secured. The former has achieved marked success, as evidenced by the prompt movement of large numbers of troops and their equipment, and the carrying of the heaviest freight traffic in history during 1941. The abandonment of obsolete lines has not met with equal success chiefly because of opposition to discontinuing the operation of unprofitable branches.

---

[19] "The Transportation of Tomorrow," by Joseph B. Eastman, *Civil Engineering*, January, 1942, p. 1.

[20] "The Public Work Reserve," by Melvin E. Scheidt, *ibid.*, October, 1941, Fig. 1, p. 577.

[21] Asst. to Vice-Pres., G. N. Ry., St. Paul, Minn.

In discussing "Railway Transportation" the author states "Track mileage reached a maximum of 429,883 miles in 1930, declining to 408,350 miles in 1939; thousands of miles of branch and feeder lines have become obsolete." The reduction of 21,533 miles of railroad from the peak mileage is by no means a complete measure of the mileage that has become obsolete; abandonments had begun before the peak mileage was reached in 1930 and are still continuing, with many miles of obsolete line yet in operation which, for the purpose of this discussion, are considered surplus mileage in the sense of unprofitable operation.

It is of interest to consider the reasons for surplus railroad mileage, some of which are as follows:

(*a*) Competitive building of mileage in an area requiring the service of only one railroad;

(*b*) An overbuilding of railroad mileage in areas where the productive capacity of the region failed to develop sufficient traffic to support the operation of a railroad, or where depletion of the natural resources left sparsely settled districts in the wake of the exhaustion of forest areas and mineral deposits; and

(*c*) Reduced utilization of railway service due to the introduction of other transportation agencies.

The provision of the Transportation Act of 1920, requiring the issuance of a certificate of public convenience and necessity for railway construction, virtually put an end to competitive railroad building in excess of transportation needs, but considerable of such mileage remains in unprofitable operation.

Many miles of branch lines were built in agricultural areas, providing a network of railroads within the practicable limit of team-haul. This resulted in a greater railroad mileage than could be operated profitably from the production of the region. In some areas prolonged periods of drought have so reduced the production of grain and livestock that the railroads serving them must operate at a loss. This is also true of branch lines that are required to continue serving communities engaging in limited agricultural production in regions formerly devoted to lumbering or mining operations which have been exhausted.

In productive regions, where highways permit all-weather motor-truck operation, most of the livestock is trucked to market along with a considerable quantity of other farm products; less-than-carload freight, petroleum products, and some coal are trucked from distributing centers to towns on the branch lines, leaving in general only carload shipments of livestock and grain to be handled by rail to terminal markets, and a limited quantity of inbound carload freight to be transported by rail, resulting in unprofitable operation. Improved highways and the use of the motorbus and private automobile have caused local passenger traffic on the railways to diminish almost to the vanishing point.

Although a great many branch or feeder lines are unable to produce any net revenue when only their own operations are concerned, it is generally held that, if some profit is shown when the contribution of the traffic of these lines to the railway system as a whole is considered, the continued operation of the line in question is in the public interest.

In some cases where light traffic or other secondary lines of competing railways were parallel or served substantially the same areas, it has been possible to reduce the surplus mileage by securing a certificate of public convenience and necessity authorizing the abandonment and removal of one of the lines and permitting its owner to operate its trains on the remaining line under a grant of trackage rights.

F. R. SCHANCK,[22] M. AM. SOC. C. E.—In presenting the subject of transportation in the United States, the author brings before the Society one of those basic enterprises, the discussion of which properly includes the broadest aspects of engineering. The consideration of such matters tends to expand the viewpoint of members beyond the rather narrow confines of purely technical engineering. It helps to remind them that they are primarily citizens of communities and of the Nation rather than simply members of an academic debating club.

As the author indicated, a thorough study of the development of transportation in the United States requires research into history. However, the writer does not believe that merely a reference to the "First Stone" of the Baltimore and Ohio Railroad brings to the subject the full light which history can furnish. Besides history, it is necessary to consider economics, geography, law, and industrial and inventive growth, not to mention finance, and politics. In fact, it appears wise to revive one's recollection of the true function of engineering. The definition runs something like this: The study and the utilization of the forces and the materials of nature for the benefit of humanity. The last five words furnish the reason for the very existence of engineers. The author does not seem to have emphasized that ideal in his brief for railroads.

One very interesting and important type of transportation in the United States is not covered by the author; that is, city "mass transportation." During the life time of many, city street cars were drawn by animals—horses, and mules; then many lines used cable traction. Soon practically all these were supplanted by electricity and now, except in a few of the largest cities, buses are used for nearly all surface transportation. Until very recently many street railway companies were constantly emphasizing the fact that passengers may be carried more cheaply by electric street railways than by any other present method. However, as the president of one of the New York surface car lines has said, when requesting from the Board of Local Transportation permission to substitute buses for electric rail cars, "The people like to ride on rubber."

The fact that mass transportation has actually passed through the initiation, the zenith of prosperous operation, and now the almost complete elimination of a universally used type of plant and equipment within a comparatively short time, gives the opportunity to analyze such a development. An unbiased and critical study by engineers of a system so nearly parallel with steam railways should give accurate and helpful data as to the probable destiny of the latter. One assumption that frequently predicates discussion of transportation development is that the system that costs the least will inevitably dominate. The fact that cost alone may not necessarily satisfy the public is demonstrated by the transitions in mass transportation.

---

[22] Cons. Engr., Portland, Ore.

Some years ago, when the term of the franchises for the street-car lines of Portland, Ore., had expired, there was such violent and widespread disagreement expressed by the citizens as to renewing the franchises that the City Commission hesitated to take any action. Finally the mayor appointed a committee of citizens with a request that this body make some suggestion as to whether the old type of franchise be offered the Street Railway Company, whether a radically different set of conditions be demanded, or whether the existing company be considered as having a status no different from any other applicant for a franchise. The writer, being a member of this committee, had access to considerable public sentiment on the matter of mass transportation. Preferences for different methods of solving the mass transportation problem of Portland did not seem to be based primarily on costs to the riders.

At this same time, the writer was chairman of a committee of the City Club of Portland which had been appointed to analyze and digest the various suggestions and programs that were advanced as the solution of the mass transportation problem. This committee spent several months in collecting data from all cities of a size comparable with Portland. The committee's position also furnished the opportunity to secure statistics as to the apparent indication that cost may not be the primary factor in the minds of the public when purchasing transportation.

Several thousand questionnaires were placed in the hands of individuals of many groups which together seemed to give a fair cross section of public opinion. These included all the employees of certain laundries, banks, department stores, service clubs, factories, and office building occupants. Such questions as their ownership of automobiles, as well as their class of work, indicated quite clearly the economic status of the individuals. The majority of every group showed that some other consideration besides the amount of fare would determine their selection of means of transportation, except the employees of an interurban street railway company which has since abandoned passenger service.

As long as the selection of a mode of transportation of either freight or passengers is a matter of personal choice, the evidence just cited seems worthy of consideration by all common carriers. The limitations of the factors described in the Transportation Act creating the Board of Investigation and Research appear too narrow for a wise report on such a basic subject. The social and cultural effects of limited or abundant transportation facilities are of the utmost importance. The restraint or the development which a particular region or community may experience by absence of impartiality in its transportation services or charges as compared to other places and a multitude of complex problems all have roots in transportation.

The author has brought each other type of transportation, whose development he has described, into its relationship to railways. He writes of "normal conditions" in which railroads require large amounts of materials for operations and expansion. This normal condition apparently means when railroads have a substantial monopoly of transportation.

To have an adequate picture of the entire history of rail transportation as it is now known, it is necessary to go back at least 50 years prior to the occasion, noted by the author, of the inauguration of the Baltimore and Ohio Railroad construction. The earlier date covers that time in the British Isles when rails were laid upon which horse-drawn vehicles transported freight and passengers, and especially coal, in some of the mining regions of that country.

Where these "rail ways" were constructed along the routes of public highways they seem to have been given the same status as any other toll road, probably with the idea that those toll payers who had their own vehicles equipped with suitable wheels could have the privilege of transporting freight over the improved roadbed. Some of the rail systems permitted the use of vehicles with ordinary type wheels; others required flanged wheels.

The unique fact that at this same time the newly invented steam engine was adapted for locomotion brought about the revolutionary changes which have resulted in the modern railway systems. When steam locomotives were used as the tractive force, it became obvious that several unrelated users could not satisfactorily operate vehicles over these improved "toll roads." The implications of the origin of railways remain even after the complete evolution of the private property idea which now almost obscures the original status. Both the right of eminent domain which railroads possess and their designation as common carriers retain the germ of the origin of railroads as public highways. Permission to construct rail toll roads and to collect revenue for their use was by grants limited in time. The fee title remained in the Crown or other sovereign. Certain of the earlier charters granted to railway companies in the United States contain language which indicates the origin of this governmental status of the railway system.

In this country especially, the evolution to private ownership has been complete so that for many decades court decisions have indicated clearly that railroads are private property. This status of private property in the hands of railroad owners makes a distinction inevitable in the treatment which the railroads must expect in their dealings with governmental bodies. The author seems not to have taken this into account in his comparison of the status and problems of railroads with water, air, and highway transportation systems. All of these are free, legally, to be used by any one wishing to do so. On the other hand, no one can use the railway except the owners.

No individual or group receives any income from the use of the highways, improved air routes, or waterways. Apparently there is no comparable basis for computing the public funds to be spent on public improvements or the taxes to be levied on private property or any other of the subjects which the author indicates are matters of concern.

Although it may sometimes appear to be unjust, yet it does seem one of the requirements of nature that "iniquity of the fathers" is visited "upon the children unto the third and fourth generation." Going back much less than three generations when the railroads were substantially in complete control of all transportation, the president of one of the largest systems was most widely known by his exclamation, "the Public be damned." Even as recently as 1900 or 1910, such apparent elementary rights, which the shippers now possess as designating a route for freight shipments, were not at all privileges assured to those who paid the bill. As indicated in the case of the preference of the public as between street cars and buses even at higher cost, the convenience of door-to-door freighting service, deliveries in a reasonable and fixed time after shipment, and more frequent services all helped to build up the trucking business at the expense of railways.

In other words, more acceptable, convenient, or cheaper transportation was provided. Just as faster, although not cheaper, shipments by rail in the early part of the nineteenth century put canal boat operators out of business, so now an improvement over railways has eliminated many branch lines and caused loss of traffic, both freight and passenger, to automobiles, airplanes, and pipe lines.

There does not seem to have been any reason why the railroad companies themselves might not have foreseen the advantages that the autotruck provides for certain types of business and have used these to supplement their rail business. Instead of this, during the first few years of autotrucking, railroads combated in every way possible the additional convenience which the trucks provided the public. After it became apparent that the truck transportation was here to stay, not infrequently railroads have expended considerable sums in payment for franchises or other intangible rights to established truck or bus operators.

The question of inequity of taxation of railroads seems to be no more complex than that by which highways are financed. Although highways are used for all types of transportation, for access, and for the general convenience of the adjacent property owners and the public, they are financed almost solely by a tax on gasoline imposed on one class of users. In fact, the construction of highways has often provided great traffic outlets for railroads. In the same manner, much of the expenditures for harbor improvements, which the author classes as competition unfair to railroads, has built up water traffic most all of which is hauled to ports by railroads. The great bulk of the foreign commerce of the United States has, in the past, been lumber, wheat, cotton, meat, and food products which involved long rail hauls. Without the improved harbors many industries and the communities they support, with the railroads benefiting, could not have reached their present magnitude.

Soon after the First World War, a Royal Commission on Transport was appointed by the British Government to study all phases of the subject. The reports of this commission are illuminating even if some conditions in Great Britain are very different from those in the United States. The authority and scope of its investigations apparently were much broader than those of the Board of Investigation and Research which the President has been authorized to appoint. The Royal Commission had in its personnel not only those technically qualified to represent various types of transportation but also those whose viewpoint was more that of the well-informed public. Of course, this later viewpoint is the one which should predominate in dealing with matters as vital to all people as transportation.

J. E. TEAL,[23] M. AM. SOC. C. E.—Since the first presentation of this paper in December, 1941, transportation conditions in the United States have changed materially. This change was first manifest in the summer of 1939, and became more pronounced after September 1, 1939, when the war in Europe was started, which resulted in industries in the United States receiving large orders for materials and supplies. When a major change occurs in industrial activity, all transportation agencies immediately feel the effect. This increased industrial activity continued to December 7, 1941, when the United States declared war.

The discussions have been enlightening, as they have revealed points omitted or overlooked by the writer and have expanded others. Because of the great change in transportation conditions, caused by the war effort, it appears to the writer that the discussion might well be terminated by emphasizing the relative importance of the various transportation agencies in connection with the war economy and let the record speak for itself.

The desire of transportation agencies is to assist in winning the war at an early date. The war economy of the United States depends largely on available means of transport. The ability of the Nation to transport men and materials overseas is of vital concern. However, the overseas shipments are greatly exceeded in volume by those within the United States, because here it is necessary to transport vast numbers of troops and military equipment from one point to another, in the process of training, and also to transport the materials required in the construction of military establishments, in the building of ships, and in the manufacture of ammunition, guns, planes, and tanks. All of this transportation for the war effort is given first consideration, of course, and the remainder of the transportation is used for the benefit of civilian activities. The civilian population now (December, 1942) finds traveling more difficult because of the greatly increased demands on transportation agencies.

At the beginning of 1942 the Nation's transportation plant and facilities consisted of approximately 233,000 miles of railway first main track; 1,960,000 freight-train cars, of which 1,685,000 were railroad owned; 38,000 passenger-train cars; 45,000 locomotives; 1,469,000 miles of improved highway, on which were operated 5,000,000 highway trucks, 140,000 buses, and 29,000,000 automobiles; inland waterways, excluding the Great Lakes, which were handling 4% of the Nation's bulk freight; and 105,000 miles of pipe lines, which were moving 10% or more. Vessels that were operated on the Great Lakes and along the coast provided transportation at low cost for large quantities of coal, oil, and lumber. Airplane transportation was increasing at a rapid rate to handle the ever-increasing passenger, mail, and express load.

As stated by Ralph Budd,[24] Hon. M. Am. Soc. C. E.:

---

[23] Prin. Roadway Engr., Board of Investigation and Research, Washington, D. C.

[24] "Transportation on the Home Front," by Ralph Budd, *Civil Engineering*, September, 1942, p. 503.

"These various forms of transportation took on the traffic load incident to war abroad and preparedness at home, as it came along, without any considerable strain simply by utilizing a larger proportion of their carrying capacity than had been needed during the preceding years. Thus for the first time they realized the benefits from the extensive improvements that had been made."

Since the outbreak of World War II, on September 1, 1939, the railroads have handled a continuously increasing traffic load, as shown by Table 10. The progressive effect of the increasing traffic load is shown by the percentage data in Cols. 3, 6, and 9, Table 10. Comparing 1942 with 1939, the cumulative freight traffic increase is shown as 26.2% in carloadings and 88.9% in ton-miles. The greater increase in ton-miles is due to the increased load per car and an increase in the length of haul. The average load per car in 1942 will be more than 4 tons greater than the average load in 1939, whereas the average haul per ton of freight in 1939 was 351 miles, and today is about 420 miles. In the passenger service, including troop movements, the number of revenue passengers carried one mile nearly doubled in 1942 as compared with 1939.

TABLE 11.—RAILROAD OWNERSHIP OF FREIGHT CARS AND LOCOMOTIVES

Date; September 1:[a]	FREIGHT CARS				LOCOMOTIVES			
	Total owned	Unserviceable		Serviceable	Total owned	In Bad Order		Serviceable
		No.	%			No.	%	
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
1939	1,650,423	224,603	13.6	1,425,820	42,848	8,381	19.6	34,467
1940	1,640,924	137,869	8.4	1,503,055	41,608	6,268	15.1	35,340
1941	1,648,502	78,044	4.7	1,570,458	41.384	4,247	10.3	37,137
1942[a]	1,738,553	44,931	2.6	1,693,622	41,444	2,157	5.2	39,287

[a] Except 1942, which is for December 1.

Table 11 shows the progress made by the railroads since September 1, 1939, in freight-car and locomotive ownership. It shows the net results the railroads have obtained from installation of new equipment and the repair of existing equipment. The main achievement has been in the reduction in number and proportion of unserviceable cars and locomotives.

The number of freight cars in bad order on September 1, 1939, was 224,603, or 13.6% of total ownership. This was reduced to 44,931 freight cars on December 1, 1942, or 2.6% of total ownership. Thus, although the total ownership of freight cars increased by only 88,130 cars, the number of serviceable units increased by 267,802 cars.

In the case of locomotives, the ownership on December 1, 1942, was less than on September 1, 1939, by 1,404 locomotives. On the other hand, the number of serviceable engines increased by 4,820 units, those in bad order having been decreased from 8,381 on September 1, 1939, to 2,157 on December 1, 1942.

TABLE 12.—IMPROVEMENT IN THE UTILIZATION OF RAILWAY EQUIPMENT

Year	FREIGHT CARS		FREIGHT LOCOMOTIVES		PASSENGER LOCOMOTIVES	
	Ton-miles[a]	Index No.	Ton-miles[b]	Index No.	Car-miles[c]	Index No.
1939	692	100.0	167,870	100.0	1,408	100.0
1940	721	104.2	178,344	106.2	1,462	103.8
1941	833	120.4	198,997	118.5	1,532	108.8
1942[d]	945	136.6	214,544	127.8	1,615	114.7

[a] Freight-car utilization, in net ton-miles per active freight-car day. [b] Freight-locomotive utilization, in gross ton-miles per active freight-locomotive day. [c] Passenger-locomotive utilization, in passenger-train car-miles per active locomotive day. [d] First six months of 1942.

It is clear, however, that the railroads could not have met the heavy traffic demands of today without improved performance. Table 12 shows the steady improvement in utilization of equipment that has occurred since 1939. With respect to freight-car utilization, the average car in 1942 has been equal to more than one and one-third cars in 1939. Freight-locomotive utilization has increased 27.8%, and passenger-locomotive utilization has increased 14.7%. The railways have been doing a good job.

Table 8 shows that the relative volume of traffic for the year 1939 aggregated 543.4 billion revenue freight ton-miles and 40 billion revenue passenger-miles. It is estimated from data in Table 10 (which were furnished by the Association of American Railroads) that railway traffic will be increased 291.6 billion revenue ton-miles, or 87.4%, and revenue passenger-miles will be increased 22.3 billion miles, or 98.7%, in 1942 compared with 1939. Reliable information is not available (as of December, 1942) as to just what the traffic will be for other carriers; however, information at hand indicates that the traffic of these agencies also will be materially increased over that of 1939. It is obvious that changed conditions due to the war effort have greatly increased the demand for transportation by the highway, waterway, pipe line, and air carriers, as well as by the railroads. All of these agencies are being handicapped by the lack of equipment, and it now seems that the gasoline shortage in the East and the rubber-tire situation may have a retarding effect on the capability of the highway carriers to continue to handle the volume of traffic now prevailing.

As previously stated, the inland waterways have been improved and modernized during the past quarter of a century. The improvements of some of them were projected in the feverish rush of World War I. World War II threatens to start a similar expansion of waterway improvements. As illustrations, construction of the Florida Ship Canal, the Lake Erie-Ohio River Canal, and the St. Lawrence Deep Seaway—each possessing strong political and commercial supporters—is being advocated earnestly by their backers, either as absolutely necessary to the war effort or as desirable "make work projects" as soon as the war is over. Therefore, it seems to the writer that an examination of previous waterway developments is appropriate at this time, and in particular the Ohio River waterway system, which is probably the most complete of any improved waterway system in the United States.

This was a subject given consideration by Committee XVI—Economics of Railway Location and Operation—of the American Railway Engineering Association (A.R.E.A.) in 1940; the following conclusions[25] were formulated at that time:

> "1—The Ohio River navigation system consists of 3,612 route miles (981 on the Ohio river between Pittsburgh and Cairo, and 2,621 on tributary streams), and represents an investment on the part of the taxpayers of the United States of some $234,000,000, and a total expenditure (as of January 30, 1938) including maintenance and a relatively small amount of unexpended appropriations, of $362,000,000. Based on the operation during 1937, a total of about 4,205,000,000 ton-miles of freight was transported on these rivers, a large percentage of which would have moved on the railroads had government improved waterways not been available.
>
> "The annual cost of transportation on these rivers to the nation is estimated at approximately $34,000,000, of which about one-half is paid or absorbed by the taxpayers and the other half by the users of the waterways.
>
> "There is no evidence of record that the users of the waterways pass on to the public in general the savings that accrue to them as compared with the rail freight rate. Waterway transportation may be cheap to the favored shipper but is costly to the taxpayers, who foot the bill for improving, operating and maintaining the locks, dams and channels."

A more recent study of this subject has been reported by C. Emery Troxel,[26] who develops some very interesting cost figures (excluding the cost paid by the shipper) representing the cost per ton-mile of all traffic on this waterway system which is borne by the government or taxpayers.

The facts presented raise questions as to the effectiveness of waterways (compared to railways) as a means of maximizing wartime transportation, and of the economic justification of most, if not all, of such enterprises at any time. Concerning these questions Professor Troxel states:

> "The presence of the Ohio Waterways thereby may relieve the pressure on railroads and improve the war effort of the country. Yet this gain would be a sort of windfall for the nation, for these waterways were developed more for peacetime than for wartime use. Such additional transport capacity, granted that it may prove convenient, might have been provided more economically by other means. * * * It is customary for

---

[25] *Proceedings*, A.R.E.A., Vol. 41, 1940, p. 149.

[26] "How 'Cheap' Is River Transport?" by C. Emery Troxel, *Railway Age*, September 12, 1942, p. 408.

> waterway protagonists to acclaim the railroad-rate reductions which follow the opening of a waterway. Though they correctly note the transportation expense reduction for some commodities and companies, they fail to recognize the possibility of contrary consequences elsewhere. Perhaps the rate reductions to meet water competition have the effect of forcing rate increases for commodities or areas where there is less competition. Or, in the event of a continuance of deficit operations, railroads may be forced to abandon parts—the weaker branches—of their systems. Communities near the waterway or elsewhere—for toll-free water transportation may provoke abandonments at inland points—may be compelled to make more expensive (for some goods) use of trucks. These effects may appear slowly, and yet they may be inevitable."

Under date of September 18, 1942, the Board of Investigation and Research transmitted its annual report to the President and the Congress of the United States, in accordance with Section 305 of Part 1, Title III, Transportation Act of 1940. In this first report the Board outlines the scope of its investigations, which include the flow of traffic, the cost and efficiency of transportation services, amount of public aids received and taxes paid by each type of carrier, labor relationships, shipper-carrier relationships, regulatory policy and practices, and interterritorial freight rates. The following statement[27] is of particular significance:

> "The coming of the war has imposed extraordinary burdens upon the national transportation system. Within a very brief period carriers which for years had suffered from insufficient traffic were obliged to expand their services to the limits of their capacity, and danger signs warning of critical shortage of transportation began to appear. This sudden shift has not, however, altered the fundamental problems of transportation, nor has it changed the essential characteristics of the various types of carriers; rather, it has focused attention upon certain aspects of these problems, demonstrating the need for adequate capacity and flexibility in transportation and making more certain than ever the prospect of far-reaching readjustments in our transportation facilities.
>
> "These emergency conditions have not diminished the significance of the problems which the Board is directed to investigate. This was recognized by the President when, by proclamation of June 26, 1942, he extended the term of the Board to its statutory limit, September 18, 1944. The proclamation declares that—an efficient transportation system is essential to the nation in peace and war, and the national interest requires the development of informed policies by which such a system may be promoted, strengthened and maintained."

The Board of Investigation and Research reports progress in its studies of relative economy and fitness, public aids, taxation, and interterritorial freight rates. Under the caption "Further Reports" appears the following:

> "The Board is proceeding as rapidly as possible with the research contemplated by the act. The entry of this country into the war has complicated the problems which the Board is directed to study, but has not changed their essential character. The scarcity of trained personnel and the burdens imposed upon the carriers by wartime demands have in some ways increased the difficulty of the Board's investigations. Yet the war has emphasized the importance of the work and has facilitated it in

---

[27] Annual Report of Board of Investigation and Research, September 22, 1942, p. 3.

some important respects. It has made available recent data concerning the capacity of our transportation facilities. It has already brought forth new operating methods and has tested expedients which otherwise could be dealt with only in theory. These experiences are of great value in considering methods of developing a national transportation system adequate for the present and future needs of commerce and national defense.

"The Board's studies of the interterritorial freight rate structure will be filed in January 1943; its report on public aids to carriers will be filed early in 1943; its report on carrier taxation will be completed by the end of the current fiscal year. Its investigations of relative economy and fitness of carriers are of such magnitude and importance as to require a longer period for completion. These further reports will contain the full findings and recommendations of the Board."

The finding and recommendations of the Board will be of national interest and may have an important bearing on the future policy affecting the national transportation economy.

STABILITY OF GRANULAR MATERIALS

By R. E. Glover,[1] Esq., and F. E. Cornwell,[2] Esq.

With Discussion by Messrs. R. G. Hennes, Stanley U. Benscoter, A. Hrennikoff, D. P. Krynine, and R. E. Glover and F. E. Cornwell.

Synopsis

Results of studies made for the purpose of developing a theory of stability for granular materials, based directly on fundamental laws of behavior, are presented in this paper. Some elementary linear solutions are obtained which are applied to the problem of estimating the stability of earth dams.

Introduction

The primary purpose of soil mechanics is to develop methods of correlating laboratory tests with the performance of structures in the field. The correlation problems for granular materials are similar, in many respects, to those for elastic materials. Methods for calculating the performance of elastic structures have received much attention and the analytical tools for making the calculations have been grouped into a "theory of elasticity." Much of the theory of elasticity is built upon the postulates of equilibrium and of geometrical continuity subject to the relation between stress and strain imposed by Hooke's law. It is important to note that simplicity of the fundamental postulates does not insure a simple solution of the correlation problem since the elastic equations, in many cases, are difficult to solve.

The equations of equilibrium are as important for granular materials as for elastic materials but it can be seen readily that the continuity condition may not be appropriate for granular materials since these can often be sheared extensively without losing their properties.

In the elastic case, it has been proved[3] that a solution to the problem of stress distribution is unique provided it meets the foregoing equilibrium and continuity requirements and, in addition, satisfies the condition peculiar to the problem. These latter conditions are usually imposed at boundaries where conditions are known and, therefore, they are called "boundary conditions."

Note.—Published in November, 1941, *Proceedings*.

[3] "A Treatise on the Mathematical Theory of Elasticity," by Augustus E. H. Love, University Press, Cambridge, England, 4th Ed., 1927, paragraph 118.

In the analysis to be described, equilibrium equations expressed in terms of stresses have been retained. The continuity condition is also retained where the stress system is such as will prevent relative movement between grains. Where slippage between grains is possible, the continuity condition has been replaced by a condition between the maximum and minimum principal stresses. This relation is the one commonly referred to as Coulomb's law, which states that resistance to shearing is compounded of an intrinsic cohesion, and a frictional resistance proportional to the normal stress acting on the plane of shear.

The trained engineer will find little that is new in this description and the methods to be described are not much more than a mathematical mobilization of relations with which the engineer has long been familiar. The inducement for the expenditure of effort, on analyses of the type described herein, comes from the possibility that the use of simplifying assumptions may be avoided and the reliability of the results thereby enhanced.

In developing a mathematical approach to the solution of any physical problem, one is faced with the necessity of reducing the problem to an exact status by means of specific definitions. It is usually necessary to replace the actual material, which is almost never continuous, by an ideal continuous material. Of course, it is desirable that, in so far as possible, the properties of the two materials be identical. In the present case, certain consequences of the granular structure of the actual material are imposed upon the ideal. Other limitations arise from purely mathematical difficulties.

In the theory of elasticity, stress is defined in terms of the resultant force transmitted across a small plane area within the body. In the present case it is expedient to modify this concept because of the presence within the voids of water under pressure. The term "stress," as used herein, is defined as the force transmitted by the contact pressures between grains over a small area divided by the area, and therefore excludes the percolation pressures.

To form the concept of stress in the granular material, pass a plane through it and find the surface that passes through no particle but which lies as close to the plane as possible. The particles on one side of the surface touch those on the other at several points, and at each of these points a force is transmitted from particle to particle. Now consider a small part of the area of the surface. The average stress on the small area is defined as the resultant of the forces transmitted from particle to particle across it, divided by the area of its projection on the plane. Conceptions of average normal and shear stresses can be formed in the same way. Since it is apparent that the diameter of the small area previously mentioned must be large compared to the diameter of a grain, in order to include enough contact points to yield a valid average, a stress computation made for a point, as designated by coordinates, will represent an average stress in the immediate vicinity of the point rather than a stress at a point.

The stress convention is shown in Fig. 1. Forces of gravity, flotation, and fluid friction, as well as an additional body force which is indicated as due to earthquake, are included. When it is desired to obtain the total force transmitted across a section, pore-pressure forces must be added.

The solution requires that every small element of volume must be in equilibrium under the stress resultants and forces that act upon it. In addition to equations of equilibrium, it is required that the stresses satisfy the equations of elasticity in those regions where the relation between stresses is such as will not permit grains to change their relative positions, and in the regions where this condition is not met, it is assumed that the relation between the principal stresses is such as to make slippage imminent on the planes of least resistance.

FIG. 1.—STRESS CONVENTION AND BODY FORCES

It should be noted that the terms "elastic" and "plastic" are used herein to describe zones in which previously stated relations between principal stresses exist and not as descriptions of types of material used in the structure. A solution consists of a distribution of stresses expressed as a function of the coordinates x and y which satisfies the conditions as stated.

NOTATION

The letter symbols used in this paper are defined where they first appear, and they are assembled for convenience of reference in Appendix I.

STRESS RELATIONS IN THE ELASTIC AND PLASTIC ZONES

Let σ be the normal stress on any plane, positive when compressive, and τ the shear stress. According to the theory of failure, which is accepted herein, it is true, for every plane at every point, that

$$|\tau| \leqq C + f\,\sigma \quad \text{.........................} \quad (1a)$$

in which C and f are positive constants, known as the cohesion and the coefficient of friction, respectively, whose values depend upon the material; and it is also true that relative sliding of the material on the two sides of the plane is incipient when

$$|\tau| = C + f\,\sigma \quad \text{.........................} \quad (1b)$$

but impossible when

$$|\tau| < C + f\,\sigma \quad \text{.........................} \quad (1c)$$

Relations 1 may be written in terms of the function

$$R = C + f\,\sigma - |\tau| \quad \text{...................} \quad (2)$$

as follows: $R \geqq 0$, $R = 0$, and $R > 0$. In Eq. 2 R is a function of the position of the point and the orientation of the plane. Let R_0 be the minimum value of R at a given point. Then Eq. 1*a*, which is satisfied everywhere, is equivalent to $R_0 \geqq 0$.

Plastic Region.—At any point where $R_0 = 0$ there must be one or more planes; it is found that there are two, for which $R = R_0 = 0$, and along which, therefore, slipping is incipient. At such a point the material will be said to be in the "plastic state," and any region at every point of which the material is in the plastic state will be called a "plastic region."

Elastic Region.—At any point where $R_0 > 0$ there is no plane along which slipping is possible, since $R \geqq R_0 > 0$; and at such a point the material is assumed to obey Hooke's law and will be said to be in the "elastic state." Any region at every point of which the material is in the elastic state will be called an "elastic region."

As a consequence of Hooke's law, certain conditions of compatibility are satisfied at all points of an elastic region. For a two-dimensional body these conditions (which are discussed at length in works on the theory of elasticity) are reduced to the single equation:

$$\frac{\partial^2 \sigma_y}{\partial x^2} + \frac{\partial^2 \sigma_x}{\partial y^2} - 2\,\frac{\partial^2 \tau_{xy}}{\partial x \partial y} = 0 \quad \text{...} \quad (3)$$

The Functions R and R_0.—Functions R and R_0 may be expressed in terms of the principal stresses or in terms of the normal and shear stresses. Let σ_1 and σ_2 be the principal stresses, positive when compressive, and σ_1 algebraically the greater; and let ϕ be the angle measured counterclockwise from the line of action of σ_1 to the plane of σ and τ. Equilibrium of the triangular element shown in Fig. 2 requires that

$$\sigma = \sigma_1 \sin^2 \phi + \sigma_2 \cos^2 \phi \quad \text{...................} \quad (4a)$$

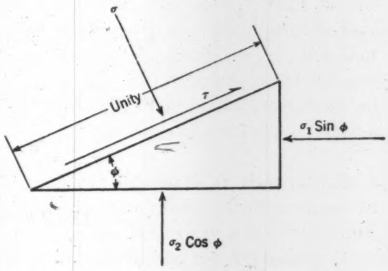

FIG. 2

and

$$\tau = (\sigma_1 - \sigma_2) \sin \phi \cos \phi \ldots\ldots (4b)$$

or

$$\sigma = \frac{\sigma_1 + \sigma_2}{2} - \frac{\sigma_1 - \sigma_2}{2} \cos 2\phi \ldots\ldots (5a)$$

and

$$\tau = \frac{\sigma_1 - \sigma_2}{2} \sin 2\phi \ldots\ldots (5b)$$

After substituting Eqs. 5 in Eq. 2 and simplifying,

$$R = C + f\frac{\sigma_1 + \sigma_2}{2} - \frac{\sigma_1 - \sigma_2}{2}(f \cos 2\phi + |\sin 2\phi|) \ldots\ldots (6a)$$

Then remembering that R_0 is the minimum of R at a given point, and that at a given point σ_1 and σ_2 are constants, one finds

$$R_0 = C + f\frac{\sigma_1 + \sigma_2}{2} - \sqrt{1 + f^2}\,\frac{\sigma_1 - \sigma_2}{2} \ldots\ldots (6b)$$

This minimum is attained when

$$\phi = \pm \operatorname{arc\,tan}\left(\sqrt{1 + f^2} - f\right) \ldots\ldots (7)$$

The two planes thus defined form the acute angle, arc tan $\frac{1}{f}$, which is bisected by the line of action of σ_1, the greater of the principal stresses. These are the planes along which slip occurs, if it does occur.

Other useful relationships, the derivations of which are omitted, are:

$$\frac{\sigma_1 + \sigma_2}{2} = \frac{\sigma_x + \sigma_y}{2} \ldots\ldots (8a)$$

$$\frac{\sigma_1 - \sigma_2}{2} = \tfrac{1}{2}\sqrt{(\sigma_x - \sigma_y)^2 + 4\,\tau^2_{xy}} \ldots\ldots (8b)$$

$$\sigma_x = \frac{\sigma_1 + \sigma_2}{2} + \frac{\sigma_1 - \sigma_2}{2} \cos 2\theta \ldots\ldots (8c)$$

$$\sigma_y = \frac{\sigma_1 + \sigma_2}{2} - \frac{\sigma_1 - \sigma_2}{2} \cos 2\theta \ldots\ldots (8d)$$

$$\tau_{xy} = \frac{\sigma_1 - \sigma_2}{2} \sin 2\theta \ldots\ldots (8e)$$

$$\tan 2\theta = \frac{2\,\tau_{xy}}{\sigma_x - \sigma_y} \ldots\ldots (8f)$$

$$\sin 2\theta = \frac{2\,\tau_{xy}}{\sigma_1 - \sigma_2} \ldots\ldots (8g)$$

and

$$\cos 2\theta = \frac{\sigma_x - \sigma_y}{\sigma_1 - \sigma_2} \ldots\ldots (8h)$$

in which θ is the angle measured counterclockwise from the x-axis to the line of action of σ_1. It frequently happens that confusion arises in the computation of θ; and it should be remembered, therefore, that: $\sigma_1 - \sigma_2$ is never negative; θ is referred always to σ_1, the greater—never to σ_2, the lesser; and θ is defined not by the value of $\tan 2\theta$ (Eq. 8*f*), but by the value of $\tan 2\theta$ and the algebraic sign of either $\sin 2\theta$ or $\cos 2\theta$. If Eqs. 8*a* and 8*b* are substituted in Eq. 6*b*, the following expression for R_0 is obtained:

$$R_0 = C + f\frac{\sigma_x + \sigma_y}{2} - \frac{\sqrt{1+f^2}}{2}\sqrt{(\sigma_x - \sigma_y)^2 + 4\,\tau^2_{xy}} \;\ldots\ldots\ldots (9)$$

COHESIONLESS MATERIAL

The types of solutions available at present are applicable only to a cohesionless material; that is, one for which $C = 0$. For such a material the law $R_0 \geqq 0$ becomes, in terms of the principal stresses, from Eq. 6*b*,

$$f\frac{\sigma_1 + \sigma_2}{2} \geqq \sqrt{1+f^2}\,\frac{\sigma_1 - \sigma_2}{2} \;\ldots\ldots\ldots\ldots\ldots\ldots (10a)$$

or, in terms of σ_x, σ_y, and τ_{xy}, from Eq. 9,

$$f\frac{\sigma_x + \sigma_y}{2} \geqq \frac{\sqrt{1+f^2}}{2}\sqrt{(\sigma_x - \sigma_y)^2 + 4\,\tau^2_{xy}} \;\ldots\ldots\ldots\ldots (10b)$$

By letting $B = \dfrac{\sqrt{1+f^2}}{f}$ Eqs. 10 reduce to

$$\sigma_2 \geqq \frac{B-1}{B+1}\,\sigma_1 \;\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11a)$$

and

$$\sigma_x + \sigma_y \geqq B\,\sqrt{(\sigma_x - \sigma_y)^2 + 4\,\tau^2_{xy}} \;\ldots\ldots\ldots\ldots\ldots (11b)$$

The equalities represented by Eqs. 11 are two ways of stating the plasticity condition, and the inequalities represent a relation that must be satisfied in elastic regions. These expressions imply, and it can be proved, that tensile stresses are impossible, that inside an elastic region neither of the direct stresses can vanish; also that inside or on the boundary of a plastic region, if either direct stress is zero, then all the stresses are zero. It follows that all stresses vanish at a free boundary, and it should be noted that any boundary subjected to water load alone is free, provided the water pressure is continuous across the boundary.

Boundary Between Elastic and Plastic Region.—It is clear that, across a boundary between an elastic and plastic region, the direct stress normal to the boundary and the shear stress tangential to the boundary are continuous, but it is not clear whether the direct stress tangential to the boundary is or is not continuous.

It appears that the theory must permit such a boundary to move as the loading on the outer boundaries of the body is varied. If the direct stress tangential to the boundary is not continuous, then, as the boundary moves, there must be sudden changes of stress at points on the boundary, and sudden movements of the particles, involving infinite accelerations. Such consequences are to be avoided, and it is postulated, therefore, that all stresses are continuous across the boundary. Of course, this postulate holds only in case the properties of the material are continuous across the boundary.

APPLICATION TO THE PROBLEM OF EARTH-DAM STABILITY

The structure to be analyzed is idealized by dividing it arbitrarily into a series of elastic and plastic regions (see Fig. 3). Odd Roman numerals (I, III, V, etc.) are used to designate regions assumed to be plastic and even ones (II, IV, VI, etc.) denote regions assumed elastic. In every case it is assumed that the inner boundaries, those joining two regions, are straight lines. The use, in the equations of inner boundaries, of arbitrary constants α and β with subscripts associating them with the elastic region involved is also illustrated. The corresponding terms for the outer boundaries (that is, numbers n_1 and n_2) used in the equations of the downstream and upstream slopes are constant, of course, for any one dam and are obtainable directly from known data.

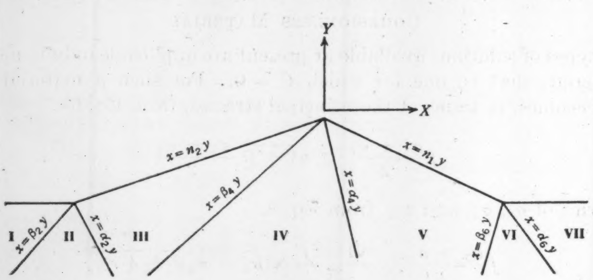

FIG. 3

Note that the problem, as illustrated, is cut into three parts in which are grouped regions I, II, III, regions III, IV, V, and regions V, VI, VII. The separate parts are referred to as applying, respectively, to the upstream toe, the dam, and the downstream toe. For each part a new system of axes, with its origin at the point common to all three regions and with the x and y axes parallel to and with the sense of those for regions III, IV, V, is used. Additional parts are needed when the slope of either fill is not uniform throughout. In such a case the actual slope is approximated by two or more sections of constant slope and then a new group is introduced at each point where there is a change.

EQUATIONS AND LINEAR SOLUTIONS FOR ELASTIC REGIONS

The forces acting on an element of the material are shown in Fig. 1. If the accelerations of the water are negligible, the equations of equilibrium are seen to be

$$\frac{\partial \sigma_x}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial u}{\partial x} + h = 0 \ldots\ldots\ldots\ldots\ldots\ldots (12a)$$

and

$$\frac{\partial \sigma_y}{\partial y} + \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial u}{\partial y} + \gamma + D_w\, e = 0 \ldots\ldots\ldots\ldots\ldots (12b)$$

The three partial differential equations (Eqs. 3 and 12) must be satisfied by any solution for an elastic region. Consider a definite region "i," and make

$$C_{2i} = \gamma + D_w e + \frac{\partial u_i}{\partial y} \qquad (13a)$$

and

$$C_{2i} C_{1i} = h + \frac{\partial u_i}{\partial x} \qquad (13b)$$

Then the general linear solution of Eqs. 3 and 12 is

$$\sigma_x = C_{2i} (a_{1i} x + a_{2i} y + a_{3i}) \qquad (14a)$$

$$\sigma_y = C_{2i} (b_{1i} x + b_{2i} y + b_{3i}) \qquad (14b)$$

and

$$\tau_{xy} = C_{2i} [- (1 + b_{2i}) x - (a_{1i} + C_{1i}) y + d_{3i}] \qquad (14c)$$

in which a_{1i}, a_{2i}, a_{3i}, b_{1i}, b_{2i}, b_{3i}, and d_{3i} are arbitrary constants.

In general, however, one does take the vertex or common point of all the regions involved as the origin of the coordinate system. With this in mind it is evident that all stresses must vanish at $x = 0$, $y = 0$. Then the solution in the elastic region "i" reduces to

$$\sigma_x = C_{2i} (a_{1i} x + a_{2i} y) \qquad (15a)$$

$$\sigma_y = C_{2i} (b_{1i} x + b_{2i} y) \qquad (15b)$$

and

$$\tau_{xy} = C_{2i} [- (1 + b_{2i}) x - (a_{1i} + C_{1i}) y] \qquad (15c)$$

In these expressions, the four arbitrary constants a_{1i}, a_{2i}, b_{1i}, and b_{2i} will be determined, along with α_i and β_i, by the boundary conditions along $x = \alpha_i y$ and $x = \beta_i y$.

The inequality $R_0 > 0$ expressed in Eq. 11b as

$$\sigma_x + \sigma_y > B \sqrt{(\sigma_x - \sigma_y)^2 + 4 \tau^2_{xy}} \qquad (16a)$$

must be satisfied in order to comply with the definition of an elastic region.

EQUATIONS AND LINEAR SOLUTIONS FOR PLASTIC REGIONS

In any plastic region "i" a solution must satisfy two partial differential equations and one algebraic equation; namely, Eqs. 12 and the equation arising from the law $R_0 = 0$. This latter equation, called the plasticity equation, is from Eq. 11b,

$$\sigma_x + \sigma_y = B \sqrt{(\sigma_x - \sigma_y)^2 + 4 \tau^2_{xy}} \qquad (16b)$$

The general linear solution of Eqs. 12 and 16b, in which C_{1i} and C_{2i} are defined by Eqs. 13, is

$$\sigma_x = - C_{2i} (C_{1i} + n - n^2 b_{1i}) (x - n y + \epsilon') \qquad (17a)$$

$$\sigma_y = C_{2i} b_{1i} (x - n y + \epsilon') \qquad (17b)$$

and

$$\tau_{xy} = - C_{2i} (1 - n b_{1i}) (x - n y + \epsilon') \qquad (17c)$$

in which b_{1i} is determined by

$$(1 + n^2)^2 b^2_{1i} - 2\left[(n + C_{1i})(n^2 - 1 - 2f^2) + 4n(1 + f^2)\right] b_{1i} + (n + C_{1i})^2 + 4(1 + f^2) = 0 \qquad (18)$$

except that the foregoing solution does not include the case corresponding to $n \rightarrow \infty$, which is

$$\sigma_x = C_{2i}\, a_{2i}\, (y + \epsilon') \qquad (19a)$$

$$\sigma_y = -\, C_{2i}\, (y + \epsilon') \qquad (19b)$$

and

$$\tau_{xy} = -\, C_{2i}\, C_{1i}\, (y + \epsilon') \qquad (19c)$$

in which

$$a_{2i} = -\left[\frac{B^2 + 1}{B^2 - 1} \pm \frac{2B}{B^2 - 1}\sqrt{1 - C^2_{1i}(B^2 - 1)}\right] \qquad (20)$$

Note that in each type of solution for a plastic region there are two cases, coming (for example) from the two solutions of the quadratic equation for b_{1i}. These are distinguished, whenever the two are different, by denoting that in which σ_x is the larger of the two values of σ_x as the passive case, the other as the active case.

As for elastic regions, the most important case is that in which the stresses are assumed to vanish at $x = 0$, $y = 0$. For such conditions,

$$\sigma_x = -\, C_{2i}\, (C_{1i} + n - n^2 b_{1i})\, (x - n\, y) \qquad (21a)$$

$$\sigma_y = C_{2i}\, b_{1i}\, (x - n\, y) \qquad (21b)$$

and

$$\tau_{xy} = -\, C_{2i}\, (1 - n\, b_{1i})\, (x - n\, y) \qquad (21c)$$

in which b_{1i} is determined by Eq. 18. Note that along $x = n\, y$ these expressions yield $\sigma_x = \sigma_y = \tau_{xy} = 0$. Another useful case where $C_{1i} = 0$ is that in which all stresses are zero along $y = 0$. Then for the active case,

$$\sigma_x = -\, C_{2i}\, \frac{B - 1}{B + 1}\, y \qquad (22a)$$

$$\sigma_y = -\, C_{2i}\, y \qquad (22b)$$

and

$$\tau_{xy} = 0 \qquad (22c)$$

and for the passive case (in addition to Eqs. 22*b* and 22*c*)

$$\sigma_x = -\, C_{2i}\, \frac{B + 1}{B - 1}\, y \qquad (23)$$

The condition that all three stresses vanish along the outer boundary is sufficient to exhaust the arbitrary constants in a plastic region. Hence the solution is then known completely in an "outer" plastic region—that is, in a plastic region part of whose boundary is part of the boundary of the structure.

Slip Lines.—The direction of the slip lines may be determined by computing the two angles θ and ϕ by formulas already presented. However, this computation may be shortened as follows: Let ψ equal the angle between the y-axis and a slip line, counted positive clockwise. Then the directions of the two families of such lines are,

$$\tan \psi_1 = \lambda_1 = -\frac{2 f \tau_{xy} + \sigma_y - \sigma_x}{2 \tau_{xy} - 2 f \sigma_y} \qquad (24a)$$

and

$$\tan \psi_2 = \lambda_2 = -\frac{-2 f \tau_{xy} + \sigma_y - \sigma_x}{2 \tau_{xy} + 2 f \sigma_y} \qquad (24b)$$

Note that if the stresses are linear, as they are in the present solutions, then λ_1 and λ_2 are constants and the slip lines are two families of parallel straight lines. It is convenient to use the exact check formula,

$$\left| \frac{\lambda_1 - \lambda_2}{1 + \lambda_1 \lambda_2} \right| = \frac{1}{f} \qquad (25)$$

CONDITIONS FOR FAILURE

In the plastic zones the stress distribution is such that slippage is imminent. This does not mean, however, that a failure by sliding can occur since the direction of slip may be toward the foundation or an elastic zone where a reserve of strength is available. Under such condition, no slip of significant magnitude can occur and the structure is stable. The existence of a plastic zone then means simply that the material in the zone has acquired all the load it can carry. Any further load must be accommodated by encroachment on the reserve in the elastic zones by a readjustment of the boundary between the elastic and plastic zones. However, if a situation arises in which a continuous slip line can be drawn beginning in one free surface and terminating in another, then there is no limitation to movement and a slide may be expected. The condition for a sliding failure may then be reduced to a question of the possibility of drawing such a line. If a set of conditions is assumed which precludes the possibility of stability, no solution can be constructed. Such a condition can be readily obtained, for example, by choosing too steep a slope. In this case, the impossibility of constructing a solution is a definite indication of instability. Cases have occurred, however, in which a failure to obtain a solution may have indicated merely that no solution exists of the type sought. It is hoped that such questions may be answered as soon as more solutions to the fundamental equations are obtained.

The type of analysis described does not lead to an evaluation of a factor of safety but to a determination of stability or instability. An idea of the reserve strength available may be obtained, however, by investigating the reserve R in the elastic zones and by studying the solution to determine whether small or large changes of loading would be necessary to produce the conditions for a slide.

APPLICATIONS

DATA

Height of dam, in ft	100
Upstream slope	1 on 3
Downstream slope	1 on 2
Coefficient of friction, f	0.7
Dry density, in lb per cu ft, γ	120

EQUATIONS OF STRESSES

Regions I and VII:

$$\sigma_x = -0.271\,\gamma\,y \qquad \sigma_y = -\gamma\,y \qquad \tau_{xy} = 0$$

Region II:

$$\sigma_x = \gamma\,(0.066\,x - 0.311\,y) \qquad \sigma_y = \gamma\,(0.176\,x - 1.108\,y) \qquad \tau_{xy} = \gamma\,(0.108\,x - 0.066\,y)$$

Region III:

$$\sigma_x = 0.099\,\gamma\,(x - 3\,y) \qquad \sigma_y = 0.344\,\gamma\,(x - 3\,y) \qquad \tau_{xy} = 0.033\,\gamma\,(x - 3\,y)$$

Region IV:

$$\sigma_x = \gamma\,(-0.008\,x - 0.244\,y) \qquad \sigma_y = \gamma\,(-0.096\,x - 0.816\,y) \qquad \tau_{xy} = \gamma\,(-0.184\,x + 0.008\,y)$$

Region V:

$$\sigma_x = -0.171\,\gamma\,(x + 2\,y) \qquad \sigma_y = -0.543\,\gamma\,(x + 2\,y) \qquad \tau_{xy} = 0.085\,\gamma\,(x + 2\,y)$$

Region VI:

$$\sigma_x = \gamma\,(-0.129\,x - 0.359\,y) \qquad \sigma_y = \gamma\,(-0.281\,x - 1.190\,y) \qquad \tau_{xy} = \gamma\,(0.190\,x + 0.129\,y)$$

FIG. 4.—TYPICAL ANALYSIS FOR EMPTY RESERVOIR

as completed and also lists data used in the computations. An outline of the solution follows.

Upstream Toe.—For region I, $C_{11} = 0$ and $C_{21} = \gamma$. Stresses were computed by Eqs. 22.

For region III, $C_{13} = 0$, $C_{23} = \gamma$, $n = 3$. Stresses were computed by Eqs. 21, using the value of b_{13} from Eq. 18 for the active case.

For region II, $C_{12} = 0$, $C_{22} = \gamma$. Stresses for this region are given by Eqs. 15. In order to evaluate the four arbitrary constants in these equations and the two arbitrary constants in the equations of the boundaries, the direct and shear stresses were equated across the boundaries—that is, across $x = \alpha_2 y$ and $x = \beta_2 y$. This led to the six simultaneous equations,

$$\left.\begin{aligned} a_{12}\beta_2 + a_{22} &= -0.27108 \\ b_{12}\beta_2 + b_{22} &= -1 \\ (1 + b_{22})\beta_2 + a_{12} &= 0 \\ a_{12}\alpha_2 + a_{22} &= 0.09886\,(\alpha_2 - 3) \\ b_{12}\alpha_2 + b_{22} &= 0.34432\,(\alpha_2 - 3) \\ \text{and} \qquad (1 + b_{22})\alpha_2 + a_{12} &= -0.03295\,(\alpha_2 - 3) \end{aligned}\right\} \ldots\ldots\ldots\ldots(26)$$

Eqs. 26 were solved and the numerical values placed in Eqs. 15. The resulting expressions for σ_x, σ_y, and τ_{xy} are given in Fig. 4. For a check of the inequality which must be satisfied in any elastic region (see Eq. 16*a*), the point $x = 0$, $y = -1$ was used, from which $\sigma_x = 0.311\,\gamma$, $\sigma_y = 1.108\,\gamma$, $\tau_{xy} = 0.066\,\gamma$, and $B = 1.7438$; then (see Eq. 16*a*) $1.409\,\gamma < \sigma_x + \sigma_y$ (as required).

Dam.—For region III the values determined in the computations for the upstream toe were applicable. This is true because of the fact that a shift in the origin of coordinates, to any point along the boundary where all stresses are zero, produces no change in the expressions for stresses. Stresses for region V were computed by the use of the same formulas and data as for region III except that $n = -2$. The stresses in region IV and expressions for the boundaries were established by equating direct and shear stresses across $x = \alpha_4 y$ and $x = \beta_4 y$. The inequality was checked as at the upstream toe.

Downstream Toe.—Stress values for region V were obtainable directly from the solution for the dam. For region VII the stresses were the same as for region I at the upstream toe. The work of obtaining the stresses in region VI and of fixing the boundaries between regions was done by equating stresses as before, only this time the boundaries $x = \alpha_6 y$ and $x = \beta_6 y$ were used.

Directions of the slip lines as shown in the various plastic regions, Fig. 4, were obtained by substituting stresses for the region in question in Eqs. 24.

Example 2. Solution of a Typical Zoned Dam of 1 on 3 Upstream and 1 on 2 Downstream Slopes, with Reservoir Full.—Fig. 5 shows the results of the analysis and data used in the computations. An outline of the procedure follows.

Upstream Toe.—In this area the percolation pressure contours are taken as horizontal and as having a hydrostatic spacing vertically. The percolation function may then be written as $u = -D_w\,(y - H)$. This gives $\frac{\partial u}{\partial y} = -D_w$ and for a value of $\gamma + D_w\,e$ of 120 lb per cu ft; then, $C_2 = 57.6$; and $C_1 = 0$. The remainder of the solution is similar to that in Example 1.

Dam.—Stresses for region III may be taken from the upstream toe solution. Region V, which is taken as dry, was computed as in Example 1. In region IV

EQUATIONS OF STRESSES

Regions I and VII:
$\sigma_x = -15.614\, y$
$\sigma_y = -57.6\, y$
$\tau_{xy} = 0$

Region II:
$\sigma_x = 3.788\, x - 17.930\, y$
$\sigma_y = 10.140\, x - 63.797\, y$
$\tau_{xy} = 6.197\, x - 3.788\, y$

Region III:
$\sigma_x = 5.695\, (x - 3\, y)$
$\sigma_y = 19.833\, (x - 3\, y)$
$\tau_{xy} = 1.898\, (x - 3\, y)$

Region IV:
$\sigma_x = 15.092\, x - 35.711\, y$
$\sigma_y = 46.984\, x - 113.32\, y$
$\tau_{xy} = -10.117\, x + 18.123\, y$

Region V:
$\sigma_x = -16.234\, (x + 2\, y)$
$\sigma_y = -51.558\, (x + 2\, y)$
$\tau_{xy} = 8.117\, (x + 2\, y)$

Region VI:
$\sigma_x = -60.195\, x - 56.423\, y$
$\sigma_y = -130.968\, x - 146.390\, y$
$\tau_{xy} = 88.790\, x + 60.195\, y$

FIG. 5.—TYPICAL ZONED DAM; ANALYSIS FOR FULL RESERVOIR

the percolation pressure contours were assumed parallel to the boundary $x = \alpha_4\, y$, so the percolation function was written as

$$u_4 = -D_w \frac{x - \alpha_4\, y}{\beta_4 - \alpha_4} \qquad (27)$$

Then

$$\frac{\partial u_4}{\partial y} = \frac{D_w\, \alpha_4}{\beta_4 - \alpha_4} \qquad (28a)$$

and

$$\frac{\partial u_4}{\partial x} = -\frac{D_w}{\beta_4 - \alpha_4} \qquad (28b)$$

When $\gamma + D_w\, e = 120$ lb per cu ft,

$$C_{24} = \frac{120\,\beta_4 - 57.6\,\alpha_4}{\beta_4 - \alpha_4} \qquad (29a)$$

and

$$C_{14} = \frac{-\,62.4}{120\,\beta_4 - 57.6\,\alpha_4} \qquad (29b)$$

The remainder of the solution is similar to that given in Example 1.

Downstream Toe.—Horizontal percolation pressure contours, spaced hydrostatic vertically, were taken in regions VI and VII. Then for these regions: $u = -\,D_w\, y$; $C_2 = 57.6$; and $C_1 = 0$.

Stresses in region V were computed for the dam assuming that it is dry. These same stresses were used when equating stresses across $x = \beta_6\, y$. This involves no inconsistency because the stresses computed for region VI are contact stresses and do not include the percolation pressure. The upward body forces due to flotation below river-bed level in zone V, however, are neglected. The details of the remainder of the procedure have been given previously.

By letting the percolation function in region VII be variable, its limiting value for stability may be determined by joining regions V and VII directly. This may be accomplished by equating normal and shear stresses across a common boundary and solving for the value of the pressure in the percolation function. This computation has been made for various conditions and the results are given in Table 3, Appendix II.

CONCLUSION

All present available solutions, of the fundamental equations that have been established in this paper, are linear in form. This definitely limits the stress systems in the various regions and makes mandatory a system of linear boundaries between regions. More general solutions are needed to avoid many of the present limitations. The present linear solutions should be considered as representing a first step in the development of a general method of approach.

ACKNOWLEDGMENTS

This method of analysis was developed in the Denver (Colo.) office of the Bureau of Reclamation, U. S. Department of the Interior, since about 1936. Among those who contributed were A. W. Adkins, E. D. Rainville, W. D. Dickenson, Jr., and W. H. Jurney. Technical studies of the office are conducted under the direction of Ivan E. Houk, M. Am. Soc. C. E., senior engineer. All designs and investigations are conducted under the supervision of J. L. Savage, M. Am. Soc. C. E., chief designing engineer. All engineering and construction work is under the general direction of S. O. Harper, M. Am. Soc. C. E., chief engineer, with headquarters in Denver, and all activities of the Bureau are under the direction of John C. Page, M. Am. Soc. C. E., commissioner, with headquarters at Washington, D. C.

APPENDIX I

NOTATION

The following symbols, used in this paper, conform essentially with "Soil Mechanics Nomenclature" approved by the Society in 1941 and published as Manual of Engineering Practice No. 22:

a = arbitrary constant (a_{1i}, a_{2i}, a_{3i}, etc.);

$B = \dfrac{\sqrt{1+f^2}}{f}$;

b = arbitrary constant (b_{1i}, b_{2i}, b_{3i}, etc.);

C = cohesion; also arbitrary constant (C_{1i}, C_{2i}, C_{3i}, etc.);

D_w = density of water;

d = arbitrary constant (d_{1i}, d_{2i}, d_{3i}, etc.);

e = ratio of voids to total volume;

f = coefficient of internal friction;

H = depth of water in reservoir;

h = horizontal earthquake acceleration force expressed as a force per unit of volume;

n_1, n_2, n_3, etc. = arbitrary constants in the equations of the outer boundaries;

R = a function representing the reserve strength to resist shear failure;

R_0 = the minimum of R;

u = percolation pressure;

x and y = rectangular coordinates;

α = arbitrary constant in the equations of the inner boundaries;

β = arbitrary constant (see α);

γ = dry weight per unit of volume;

ϵ' = an arbitrary constant;

θ = angle of the x-axis to the line of action of σ_1, counted positive counterclockwise;

λ = tangent of the angle ψ;

σ = normal component of stress, positive when compressive;

σ_x and σ_y = normal stresses on planes normal to the x and y axes respectively;

τ = shear stress;

τ_{xy} = shear stress in direction of x on plane normal to y;

ϕ = angle from the line of action of σ_1 to the plane under consideration, counted positive counterclockwise;

ψ = angle from the y-axis to the slip lines, counted positive clockwise.

Table 1 can be used to investigate the stability of slopes in the following cases:

(*a*) Downstream slopes of dams below the point where the phreatic line emerges;

(*b*) Upstream slopes following a rapid drawdown; and

(*c*) Slopes of cuts or fills when saturated.

TABLE 2.—LIMITING SLOPES FOR VARIOUS VALUES OF C_1

The type of failure contemplated is shown in Fig. 6(*b*) to consist of a sliding of material down the slope. The fill material is assumed cohesionless. The percolation pressures for saturated slopes are assumed to have a hydrostatic distribution in the vertical direction. The numbers in Table 2 represent the steepest slopes that can be expected to remain stable under assumed conditions.

The quantity C_1 is defined for wet material as

$$\frac{\text{Fraction of gravity} \times \text{wet density}}{\text{Wet density} - \text{density of water}},$$

and for dry material as fraction of gravity.

Table 3 is useful for evaluating the effects of excessive uplift or percolation pressure gradients at the downstream toe of earth dams. It is also useful for estimating the intensity of the upward percolation pressure gradients necessary to produce piping.

The computations indicate that a slide should occur at the downstream toe before actual piping is observed. However only a small difference is indicated between the gradients necessary to cause sliding and piping, and, if the conditions were local, it would be reasonable to expect the piping phenomena to appear first.

The individual entries in Table 3 are the upward percolation pressure gradients in pounds per cubic foot necessary to produce failure, as shown in Fig. 6(*c*). The gradients necessary to produce piping are indicated in that part of the table marked "Horizontal."

DISCUSSION

R. G. Hennes,[4] Assoc. M. Am. Soc. C. E.—In this paper the authors have advanced the development of soil mechanics and have, perhaps, somewhat shifted the course of that development. All tools available to the engineer for the design or analysis of earthwork and foundations are notably of limited application. Each new tool supplements rather than supplants the older. In the opinion of the writer stability analysis by summation of forces along a curved potential slip surface will remain the more convenient and more reliable method for estimating the stability of earth slopes. Quite possibly, the accuracy of the conventional procedure can be improved by determining the distribution of normal pressure along the slip curve by the proposed method of analysis, instead of by assuming a vertical pressure at each point proportional to the height of the overlying column of earth.

In studying the stability of the foundation of embankments the new method offers opportunity for improvement over solutions that depend upon formulas based on the assumption of a semi-infinite solid, by providing a better approximation of stress distribution over the base of the embankment.

The authors state (see "Introduction") "that the terms 'elastic' and 'plastic' are used herein to describe zones * * * and not as descriptions of types of material used in the structure." There is danger that the casual reader might construe this statement to mean that the validity of the analysis is independent of the elastic properties of the material, whereas actually such is not the case. The authors have not freed the soil analyst from the necessity of pretending that sand and a gravel follow Hooke's law. This they recognize elsewhere in the paper. The assumption that stress is proportional to strain, of course, is common to all the usually accepted equations for stress distribution; but the error thus introduced is less consequential than in the present case when, as in consolidation studies, the object of the analysis is the computation of relatively small pressure changes that occur at considerable depth due to a surface loading. In the latter case only a small part of the stress-strain curve is involved, and this short arc might reasonably be replaced by a straight line. On the other hand, by its very nature a stability analysis of an earth dam presupposes the possibility of stress intensities ranging in value from zero at a free boundary to maximum resistance in plastic zones. The curvature of the stress-strain graph for such a stress range in an embankment cannot be ignored without adversely affecting the validity of the analysis.

It is to be hoped that further development of the authors' attack on the problem of stability may introduce a substitute for Eq. 3. It appears to the writer that triaxial compression tests provide grounds for believing such a development at least a possibility. Data from a limited number of triaxial tests on sand performed at the University of Washington at Seattle, Wash., indicate that, for a given lateral pressure, the major part of the axial stress-strain curve can be fairly well described by the equation

---

[4] Associate Prof., Civ. Eng., Univ. of Washington, Seattle, Wash.

$$\epsilon = \zeta^{\frac{\sigma - n}{m}} \qquad (30)$$

in which ϵ represents strain, m and n are constants for the given test, and ζ is the base of natural logarithms. The next step would be to formulate an expression for strain involving both axial and lateral pressures.

Eq. 3 can be obtained by substituting for strain in terms of stress in the equation:

$$\frac{\partial^2 \epsilon_x}{\partial y^2} + \frac{\partial^2 \epsilon_y}{\partial x^2} - \frac{\partial^2 \epsilon_{xy}}{\partial x \, \partial y} = 0 \qquad (31)$$

If more thorough investigation should confirm the writer's hypothesis that there is available a better approximation of the facts than Hooke's law, then substitution of the former in Eq. 31 would provide a basis for improving upon Eq. 3, and would possibly lead to more realistic solutions than Eqs. 15.

It is true that such a development, if successful, would increase somewhat the amount of laboratory work prerequisite for mathematical analysis. This in itself would be a healthy situation. The general adoption of more rigorous mathematical methods has a tendency to obscure the dependence of all analysis on the accuracy of the basic physical measurements. Enforced reliance on the laboratory serves to modify overconfidence engendered by mathematical precision, while at the same time it helps to justify use of these same theoretical refinements.

STANLEY U. BENSCOTER,[5] JUN. AM. SOC. C. E.—The stress analysis of a cohesionless embankment, which the authors have presented, is a definite step forward in the knowledge of the behavior of granular materials. Many contributions, both theoretical and experimental, in this field of stress analysis are needed to create a reasonable conception of the state of stress at all points within a granular mass. This field has been neglected too long, most probably because of the supposedly insurmountable mathematical difficulties involved in dealing with a granular mass. If physicists and aeronautical engineers have been able to treat, mathematically, the behavior of groups of particles having variable velocities in thermodynamics and aerodynamics, soil physicists certainly should be able to treat, mathematically, groups of particles having variable masses. It is almost certain that statistical methods and other branches of advanced mathematics will find application eventually in the stress analysis of soils.

The authors have obtained a solution for stresses in an embankment which is possible of existence so far as can be determined from the geometry of a Mohr diagram and the assumption of a failure law representable as a straight line passing through the origin of the Mohr axes. The division of the embankment and foundation into elastic and plastic regions offers an interesting approach to the problem. The reported behavior of the elastic regions is reasonable since they decrease with increasing height of the embankment. The concept of the reserve strength R is valuable and should find much application in the future.

---

[5] Structural Design Section, Bridge Branch, U. S. Engrs., Fort Belvoir, Va.

The geometry of a Mohr diagram yields a quadratic algebraic equation (Eq. 11*b*) relating stresses and the internal friction coefficient in a plastic region. The authors have shown that linear expressions for stresses can be found which satisfy this equation and the two equations of equilibrium of an element. As the authors state, future investigations must be made to find the possibilities of expressing stresses in a plastic region by higher degree polynomials or transcendental functions. This suggests that several solutions may be found for stresses that are possible of existence; and there will probably be a need for one or more additional laws to govern the solution before the correct one (or the most probable one) can be chosen.

If the stresses are expressed in terms of an Airy function, thus assuring equilibrium of elements, the quadratic algebraic equation becomes a quadratic differential equation. Prof. Theodor von Kármán, M. Am. Soc. C. E., drew attention to this equation as one among many non-linear differential equations with which the engineer is struggling.[6] It seems strange that government engineering agencies interested in the behavior of soil are not financing a program of mathematical research in the behavior of granular masses.

Another manner of dealing with the non-linear equation governing stresses in a granular mass is the use of the principal stress lines as a coordinate system. In this orthogonal curvilinear system the shearing stress vanishes and the non-linear equation becomes linear. The resulting equation is merely a proportionality relation between the principal stresses as given by Eq. 11*a*. A simple example will illustrate: Consider the two dimensional polar coordinate system to form a set of principal stress lines in a granular mass and the body forces to be negligible. The shearing stress $\tau_{r\theta}$ is zero at all points, and the Mohr diagram reveals that

$$\sigma_r = K\,\sigma_\theta \quad \text{(32)}$$

in which K is Rankine's coefficient, either active or passive. The formulas for σ_r and σ_θ, in terms of an Airy function, are

$$\sigma_r = \frac{\partial^2 F}{\partial r^2} \quad \text{(33a)}$$

and

$$\sigma_\theta = \frac{1}{r}\frac{\partial F}{\partial r} + \frac{1}{r^2}\frac{\partial^2 F}{\partial \theta^2} \quad \text{(33b)}$$

Assuming symmetry about the origin, try the following simple stress function,

$$F = A\,r^n \quad \text{(34)}$$

Differentiating to obtain σ_r and σ_θ and substituting in Eq. 32:

$$\sigma_r = p\left(\frac{r}{a}\right)^{K-1} \quad \text{(35a)}$$

and

$$\sigma_\theta = \frac{p}{K}\left(\frac{r}{a}\right)^{K-1} \quad \text{(35b)}$$

In Eqs. 35, p is the value of σ_r at $r = a$. These formulas (represented graphically in Fig. 7) indicate the distributions that are possible in a solid or hollow cylinder of dry sand acted upon by a uniform external pressure. The inside pressure of the hollow cylinder may vary between minimum and maximum values. If the inside pressure has an intermediate value, the internal stress distribution is not known. This may be a statistical problem rather than one in elasticity. For the solid cylinder, Curve II must be rejected since it becomes infinite at the origin. Curve I gives a possible stress distribution; yet it is certainly questionable.

---

[6] "The Engineer Grapples with Nonlinear Problems," by T. von Kármán, *Bulletin*, Am. Mathematical Soc., Vol. 46, No. 8, August, 1940, pp. 615–683.

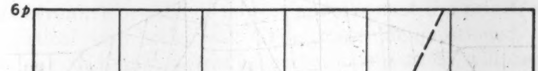

FIG. 7.—VALUES OF σ_r

The state of stress at a point in a body, in the two-dimensional case, may be completely defined by giving the stress circle on a Mohr diagram and the directions of principal stresses. The directions of principal stresses at all points within the body may be represented by drawing the principal stress lines. Thus it is apparent that investigators should strive to find laws governing the shape and location of principal stress lines. Today they know only that these lines form two orthogonal curvilinear systems which are continuous even through boundaries between elastic and plastic regions. They are not necessarily representations of harmonic functions, or solutions of La Place's equation, as one might be tempted to hope. In this connection it is interesting to note that, in 1941, M. A. Sadowsky[7] showed that in perfectly plastic behavior (no internal friction) principal stress lines form an equi-areal pattern. In elastic bodies these lines must be parallel and perpendicular to unloaded surfaces. In a granular mass this may not be true.

The principal stress lines for Example 1 (Fig. 1) may readily be drawn as shown in Fig. 8. These lines must be questioned, with a view toward encouraging further study, because they are not parallel and perpendicular to the embankment surface. If the soil contains the slightest amount of cohesion, this orthogonal boundary condition must be satisfied since a stress circle can then be drawn on a Mohr diagram passing through the origin and tangent to the limiting line. It is possible that for a granular cohesionless mass the failure law should be represented by a stair-stepped line passing through the origin, but with extremely small steps. If such were true, a tiny circle could then be drawn tangent to the limiting line and passing through the origin of the Mohr axes. This would demand the aforementioned orthogonal boundary condition.

[7] "Equiareal Pattern of Stress Trajectories in Plane Plastic Strain," by M. A. Sadowsky, *Journal of Applied Mechanics*, Vol. 8, No. 2, June, 1941, pp. A-74–A-76.

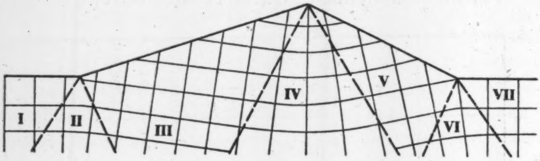

Fig. 8

In an attempt to sketch a set of principal stress lines orthogonal to the boundary one may try a set of circular and radial type lines. If an attempt is made to picture the changing shape of these lines as the height of the embankment is increased from zero to a maximum, this set of lines is rejected for a set of the type sketched in Fig. 9. These lines correspond to a non-linear solution. A few interesting observations can be made from this set of principal stress lines, assuming that the embankment has the maximum possible height. At point A, Fig. 9, the principal stress σ_1 will be the minimum principal stress, whereas at point B the stress σ_1 is the maximum principal stress. Thus some point between A and B, on any path that may be chosen, is an isotropic point or one at which $\sigma_1 = \sigma_2$. At this point, Mohr's circle degenerates to a point and there are no shearing stresses in any direction. Similarly, at point C, σ_2 is the minimum principal stress and becomes the maximum at point D. The trajectory of isotropic points might appear as curve EFG. This curve would probably appear first around the fillets and expand from there to its final position as the height of the embankment is increased. Instinctively one expects the plastic state to develop around the fillets from stress concen-

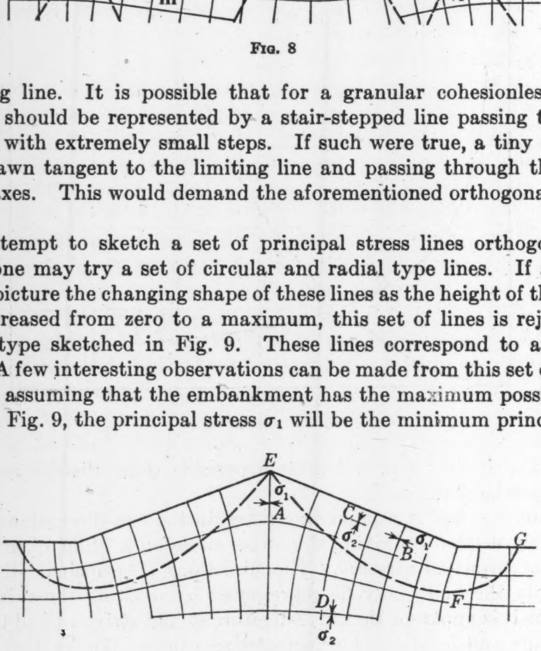

Fig. 9

tration as it occurs in elastic bodies. Heavy thrusts at the toe and heel, parallel to the surface, are in agreement with M. Frontard's solution.[8] The trajectory of isotropic points should lie within a band of elastic-state stress although the stress in such a band may be a matter of statistical mechanics rather than elasticity.

If the author's solution were applied to a symmetrical embankment constructed to maximum possible height, it appears that the principal stress lines would be vertical and horizontal. This must be questioned. This writer believes that at maximum height of embankment there will be a maximum amount of curvature and rotation of principal stress lines, which is another way to express "arching" action. The authors find Rankine's state of stress in regions I and VII of Example 1, whereas the truth would be a natural state with "at rest" pressures. This is a minor criticism. It is not apparent how the elastic and plastic regions extend downward into the foundation below the region shown in Fig. 4. The linear solution presented seems to be reasonable at an external corner, or apex of an embankment, but must be questioned when applied to a reentrant corner or fillet since it does not appear to predict the expected stress concentration.

The comments presented in this discussion are not intended to be critical of the solution presented by the authors, but rather they are meant to assist in stimulating increased interest in dealing with soil-stress problems by mathematical theory. Attention might be called to the fact that, at present, soil analysts are unable to detect experimentally the state of stress in a granular mass at various points. Hence there is no manner of proving by the "scientific method" that a given solution is true. So long as investigators are content to struggle with metallic pressure cells they will make little progress. There is great need for creative thought in both the experimental and theoretical solution of problems in the stress analysis of soils.

A. Hrennikoff,[9] Assoc. M. Am. Soc. C. E.—The novel approach to the problem of stability analysis of cohesionless granular materials, presented in this paper, is interesting.

The granular mass is visualized by the authors as divided into alternate elastic and plastic zones. The state of stress in the former obeys Hooke's law and is governed by the equations of equilibrium (Eqs. 12) and by the equation of compatibility or continuity, which for elastic materials takes the form of Eq. 3. The state of stress in the plastic regions is characterized by impending sliding at every point in the region, and is subject to the plasticity equation (Eq. 16) in addition to the equations of equilibrium (Eqs. 12), whereas Eq. 3 does not apply since the continuity has been broken. In these equations, allowance is made for the pressure of percolating water and for the constant horizontal earthquake acceleration. Expressions obtained for the stresses are linear functions of the coordinates.

The foregoing presents an outline of the proposed method, and now some of the limitations of the assumptions involved in it will be discussed.

[8] "Calculs de Stabilité des Barrages en Terre," by M. Frontard, *Transactions*, Second Congress on Large Dams, Vol. IV, pp. 243–293.

[9] Asst. Prof., Civ. Eng., Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

1. *Uniqueness of Solution.*—A disconcerting feature of the problem of stress analysis in a mass of soil consisting of a combination of elastic and plastic regions is the multitude of the states of stress that may be found for the same exterior boundary conditions after some more or less artificial conditioning of the soil mass. This important feature distinguishes sharply the problem discussed here from the problems of the theory of elasticity, in which the solutions are unique.

To illustrate this point, consider a dam similar to the one shown in Fig. 4 and assume, for the sake of simplicity, that it is symmetrical about the vertical plane. Imagine, now, two adjacent thin, vertical, smooth walls cutting through the dam along the axis of symmetry and dividing it into two equal parts. Holding the right wall for the time being in place, move the left wall horizontally to the left. A passive plastic state of stress forms now in the soil in the vicinity of the wall, and this plastic region extends gradually to the left, as the stresses increase with further advance of the wall. Next, leave the left side of the dam at the location it has reached and perform a similar operation on the right half by moving the right wall an equal amount. When the soil is so conditioned, eliminate the central gap between the two halves of the dam by moving one of the parts, together with its foundation, toward the other, and after that withdraw the walls. The two latter operations need not change the state of stress previously created in the two halves of the dam. Likewise wall movements may be imagined in the directions away from the soil creating an active plastic region in the middle of the dam. An infinite number of similar but unsymmetrical movements may also be conceived leading to a wide variety of the resultant states of stress, every one of which, no matter how artificial may be its origin, satisfies the same differential equations of equilibrium, compatibility, and plasticity, and the same exterior boundary conditions, as the solutions found by the proposed method.

Most of these theoretically conceivable states of stress bear no resemblance to the natural state resulting from the actual conditions of construction of the embankment, application of loads, and the character of possible failure.

It seems likely that the natural state of stress in the dam, as distinct from these artificial states, is also not unique in view of the influence of such rather indefinite factors as settlement, bulking, and shrinkage caused by temperature and moisture changes; but the range of such fluctuations in the natural state should not be wide.

This discussion leads to the conclusion that a solution of the differential equations cannot be accepted even as an approximate solution of the embankment problem, not to mention an exact solution, without at least demonstrating first by some appropriate qualitative analysis that such solution is reasonable under the given conditions. This qualitative investigation of the problem with the view to placing the elastic and plastic regions into locations where they are likely to develop, and of assigning to the latter the active or passive states as may be demanded by the circumstances, is completely overlooked in the method proposed. A stereotyped assumption of three regions, two plastic on the outside and one elastic between them, is used instead at every point of break in slope, and apparently under all circumstances—an assumption very convenient from the mathematical point of view, but totally unjustified physically.

Referring to the specific examples presented in Figs. 4 and 5, the presence of plastic states in regions I and VII above and below the dam seems particularly objectionable, resembling too much the generally discarded Rankine's theory of earth pressure. Also one does not see any reason for the existence of plastic states in zones III and V of Fig. 4. A dam with slopes as low as those shown in this example, and subjected to no loads other than its own weight, should, it would seem, be in an elastic state throughout.

If the stress pattern found by the proposed analysis may thus be deemed to "fall short of the mark," so the possible contention that the method answers the question of stability or instability of the embankment must likewise be considered untenable in view of the arbitrariness of location of the elastic and plastic regions.

2. Linear Variation of Percolation Pressure.—Such linear variation is assumed throughout the granular mass, as is implied in the form of the expressions for the integration constants, Eqs. 13*a* and 13*b*, making the flow lines of the percolating water straight and parallel in each region. This simple but unrealistic assumption misrepresents the effect of water and greatly reduces danger to stability arising from convergence of the flow lines and from the related phenomena of boiling and piping at the toe of the dam.

3. Hooke's Law.—Some error results from the application of this assumption to the elastic regions for the following reasons:

(*a*) The stress-strain relationship for the soil is not quite linear;

(*b*) The curve of unloading does not completely coincide with the curve of loading;

(*c*) There is some uncertainty about the legitimacy of applying the compatibility equation to soil, since this condition implies preservation of elastic continuity of deformations throughout all the past history of the soil mass from the unloaded condition to its present state—that is, through the period of construction, settlement, and the following volume fluctuations caused by temperature and moisture changes.

This uncertainty is not removed by the fact that, in the method proposed, the compatibility condition does not contribute to the results, being satisfied automatically by any linear solution for stresses. It must be admitted, however, that compliance of the soil with Hooke's law has been postulated by many investigators.

4. Elastic and Plastic Regions.—When loading decreases or reverses, the regional boundaries between the elastic and plastic zones undergo some shifting. A region that was formerly plastic but is no longer so after the load change is neither elastic nor plastic in the sense used by the authors, since the limiting sliding condition exists no more, and at the same time the compatibility equation does not hold in view of the continuity having been broken during the plastic stage. This consideration seems to invalidate the applicability of the method to the conditions that involve a reversal or a substantial change in the character of the loading. Such conditions are present in an earthquake or in the case of a sudden drawdown in a reservoir retained by the earth dam—cases which the authors apparently list within the scope of their theory.

5. Continuity of Stresses.—The assumption of continuity across the elastic-plastic boundaries of the direct (normal) stresses parallel to the boundaries has not been substantiated and appears improbable.

Some minor inconsistencies and obscurities in presentation may also be mentioned.

In Example 2 it is difficult to interpret physical conditions corresponding to the solution given in Fig. 5. Judging by the pressure contours there seems to be a lack of equilibrium in the water conditions at the boundary of zones V and VI. Again, the part played by region V with regard to percolating water is puzzling. This region seems to be composed of a very pervious material through which the water coming from region IV falls as through a chute. This naturally raises the questions: Where does this water go, and how can this situation be reconciled with the presence of pressure head in regions VI and VII?

Referring again to Fig. 5, it appears that the condition of equality of the boundary stresses at the border of zones II and IV is not satisfied. The same difficulty arises also in other places.

As the authors correctly point out, the state of stress in any elastic region must satisfy the inequality (see Eq. 16*a*) $R_0 > 0$. It is insufficient, however, to check this inequality at an arbitrary point, as the authors do, without proving that the function R_0 retains the same sign throughout the entire region.

It is not clear whether the data presented in Appendix II are based on the theory proposed; and, in case they are, how they are derived from it.

The foregoing reasons lead the writer to the belief that the proposed method of analysis of stresses in granular materials is unsatisfactory in view of its highly speculative nature and arbitrariness. However, this conclusion should not minimize the credit due the authors for the novelty of approach and mathematical ingenuity in attacking a baffling engineering problem.

D. P. KRYNINE,[10] M. Am. Soc. C. E.—The method of analysis described in this interesting paper consists in subdividing an earth dam into several regions by straight lines passing through the three vertexes of the triangle representing an idealized dam. These regions in alternate order are assumed to be "plastic" and "elastic," the difference between them being that the "plastic" regions are assumed to be on the point of losing "stability" by shear, whereas there is no shear danger in the "elastic" regions. As the authors themselves state, these terms do not define the type of the material. In fact, the latter, in general, is neither plastic nor elastic. It is regrettable that this inaccurate, though common, terminology has been adopted.

If an earth mass fails, it is generally due to a deficiency in lateral support. A vertical pressure requires a corresponding amount of horizontal pressure for stability. The "plastic" regions are brought to the state of incipient motion by so changing both the vertical and the horizontal pressures as to just satisfy Mohr's condition of failure.

[10] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

Existing Methods of Analysis of Earth Structures.—The existing methods of analyzing earth structures may be subdivided into two main classes: (*A*) Methods by which stability is checked without computing stresses at all individual points of the earth mass; and (*B*) methods by which such stresses are computed.

Methods of Class (*A*).—A geological section of the locality should be traced, and the cross section of the earth structure located on it. For this purpose the general dimensions of the earth structure are first chosen mostly from experience.

From the study of the geological section and the cross section of the structure the designing engineer tries to answer the question: "What might happen to my structure?" As Hardy Cross, M. Am. Soc. C. E., frequently says in his lectures, this question should be answered by any designer analyzing his structure—in any branch of structural design. The most common case of possible failure of an earth structure is sliding along a more or less regular surface (failure line) which in cross section is generally assumed to be an arc of a circle (see Fig. 10). The analysis should be made for all possible cases of separation of part I of the structure (hereafter termed "wedge") from the remaining part II. Conditions of equilibrium for the case of incipient motion of wedge I are established, and the safety factor found.

This approach is deficient mostly because of unwarranted assumptions that must be made as to the distribution of the shearing stress and the shearing resistance along the assumed failure line AB. The methods of this class are very valuable, however, from several other points of view. Since wedge I is considered as a solid non-deformable body, no knowledge of stresses within it is needed. Furthermore, in establishing the shape of a failure line, the designer never loses sight of the actual physical conditions of both the structure and its foundation. An appreciable percentage of earth-structure failures are foundation failures, and one of the principal aims of the designer is to avoid them. Among the methods of class (*A*) the so-called "Swedish method" and the "ϕ-circle method"[11, 12] should be mentioned.

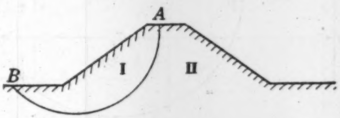

FIG. 10.—SEPARATION OF PART I OF A STRUCTURE FROM PART II ALONG THE FAILURE LINE AB

Methods of Class (*B*).—The writer limits himself to mentioning two methods of this class, both emanating from the Bureau of Reclamation. In one of them[13] the vertical normal stress, σ_y, equals the weight of the material above the given point, as in the Swedish method, and to take care of the horizontal normal stress a "compaction factor" is introduced. There are correction stresses designed to make the stresses satisfy the boundary conditions. Shearing stresses are checked against the shearing strength of the material, taking into account both friction and cohesion. In this way the factor of safety at

different points of the dam is computed, and necessary corrections are introduced into the preliminary design of the structure.

The peculiarities of the method described in the paper as compared to the method by J. H. A. Brahtz, just outlined, are the following: (*a*) Cohesion is not taken into consideration; and (*b*) there is no evaluation of a factor of safety, but simply a determination of what the authors call "reserve of strength" in the "elastic" regions. Since the "plastic" regions used in this method are those in which a failure is likely to occur, the method in question approaches the methods of class (*A*) more closely than does that of Brahtz.

Incipient Motion in "Plastic" Regions and Mohr's Circle.—If the stresses σ_x, σ_y, and $\tau_{xy} = \tau_{yx}$ at a point are in equilibrium, the ends of the vectors representing these values (σ_x = BC, σ_y = DE, $\tau_{xy} = \tau_{yx}$ = F′ E = CF, Fig. 11(*a*)) are located at a circle termed, as is well known, Mohr's circle. Vectors BC and DE are plotted horizontally from a vertical line BAD, A being a point located in the horizontal line passing through the center of the circle, O. Trace a line AG, its slope being equal to the coefficient of friction of the given earth material, *f*. In other words, make the angle GAO equal to the angle of friction. The point in question belongs to a "plastic" region if Mohr's circle touches line AG as in Fig. 11. If Mohr's circle is located below line AG and does not touch it, the point in question belongs to an "elastic" region.

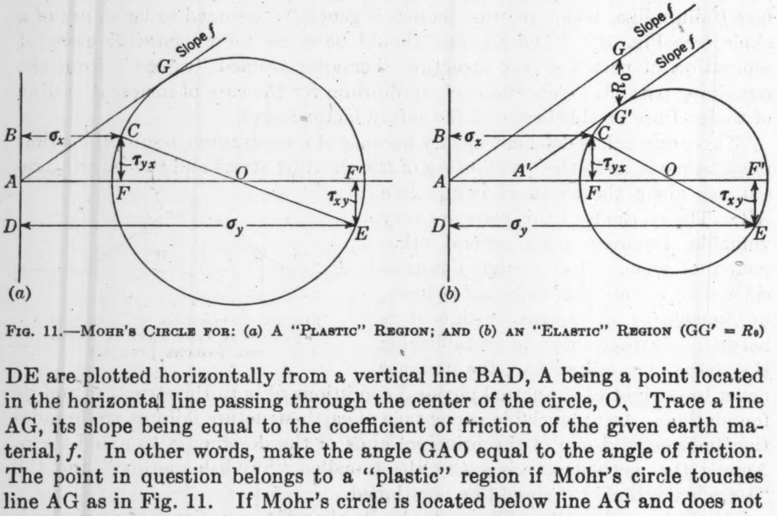

FIG. 11.—MOHR'S CIRCLE FOR: (*a*) A "PLASTIC" REGION; AND (*b*) AN "ELASTIC" REGION (GG′ = R_0)

Mohr's circle also may be constructed readily for the case of a cohesive material ($C > 0$). All formulas of the paper from Eq. 4*a* to Eq. 11*b*, inclusive, may be directly, or practically directly, seen on Mohr's circle. No doubt these equations are correct, but most of them as represented in an analytical form are not necessary for the purposes of the paper. In particular, R (Eq. 6*a*) is nothing else but the vertical distance between different points of Mohr's circle and line AG. Its minimum value, function R_0 (Eq. 6*b*), is the vertical distance between parallel lines AG and A′G′, the latter being tangent to the circle (Fig. 11(*b*)).

The values of the vertical pressure, σ_y, and the horizontal pressure, σ_x, to be used in the construction of Mohr's circle, should be corrected for percolation and earthquake. The vertical and horizontal components of the force of percolation, per unit of volume of the structure, are denoted by $\frac{\partial u}{\partial y}$ and $\frac{\partial u}{\partial x}$ in the paper. The vertical component $\frac{\partial u}{\partial y}$ ("uplift") acts against gravity. The symbol C_2 as used in the paper is the unit weight of dry earth material, plus the weight of moisture in pores, if any, minus uplift if any (Eq. 13*a*).

The horizontal component of the percolation force, $\frac{\partial u}{\partial x}$, and the horizontal force of earthquake, *h*, per unit of volume of the dam, decrease the lateral support. The algebraic sum of these two quantities, designated by $C_1 C_2$ in the paper, is given per unit of volume of the dam. It must be recomputed per square unit of the cross section of the dam as shown hereafter.

Differential Equations Are Not Necessary in "Plastic" Regions.—The use of differential equations to compute stresses in "plastic" regions may be avoided by using the following simple procedure. Refer to Fig. 12(*a*) in which *x* and *y* correspond to the point where stresses are to be computed. Cut from the dam a vertical prism ABCD having DC = 1 sq unit for base, this "unit" being very small. The given point is supposed to be at the middle of this base. The latter carries the vertical volume forces of the prism ABCD, which amount to

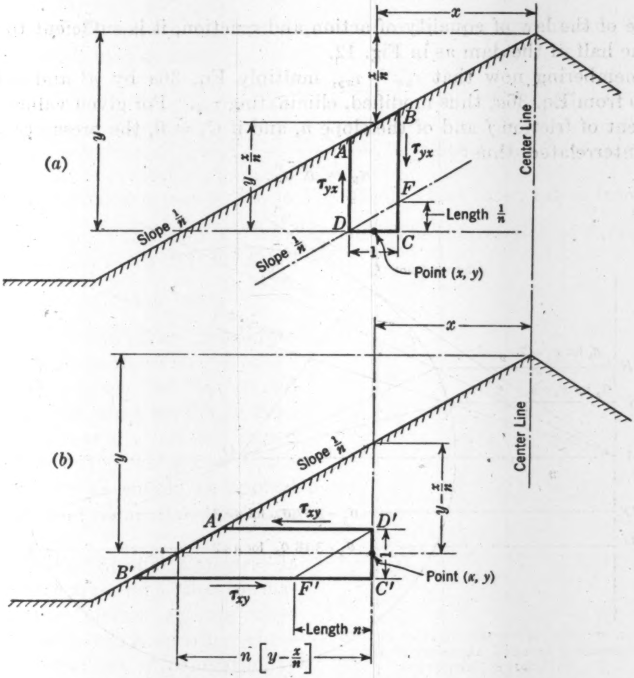

FIG. 12.—NORMAL STRESSES AND SHEARS IN A "PLASTIC" REGION

$C_2\left(y - \frac{x}{n}\right)$, this being the absolute value of those forces. In addition, there is an excess of shearing stress, τ_{yx}, acting along area FC $= \frac{1}{n}$ sq units, since the shearing stresses along areas AD and BF are balanced. Hence, the vertical pressure, σ_y, at point (x,y), is:

$$\sigma_y = -C_2\left(y - \frac{x}{n}\right) + \frac{1}{n}\tau_{yx} = \frac{C_2}{n}(x - n\,y) + \frac{\tau_{yx}}{n} \ldots\ldots (36a)$$

In a similar manner, Fig. 12(*b*) represents a horizontal prism A′B′C′D′ cut from the dam, the given point (x,y) being at the middle of its base D′C′ = 1 sq unit. Fig. 12(*b*) is a complete analogy of Fig. 12(*a*), and the horizontal pressure at point (x,y) is:

$$\sigma_x = C_1\,C_2\,n\left(y - \frac{x}{n}\right) + n\,\tau_{xy} = -\,C_1\,C_2\,(x - n\,y) + n\,\tau_{xy} \ldots (36b)$$

Because of the law of equality of action and reaction, it is sufficient to study only one half of the dam as in Fig. 12.

Remembering now that $\tau_{yx} = \tau_{xy}$, multiply Eq. 36*a* by n^2 and subtract Eq. 36*b* from Eq. 36*a*, thus modified, eliminating τ_{xy}. For given values of the coefficient of friction f and of the slope n, and if $C_1 = 0$, the pressures σ_y and σ_x are interrelated, thus:

$$\sigma_y = K\,\sigma_x \ldots\ldots\ldots\ldots (37)$$

E

FIG. 13.—RATIO BETWEEN THE VERTICAL AND THE HORIZONTAL NORMAL STRESSES IN A "PLASTIC" REGION (CASE $C_1 = 0$; FIGS. 4 AND 5)

in which K is a constant to be measured on Mohr's circle (Fig. 13). First draw a horizontal line AO and a line AG with a slope $f = 0.7$ (as in the examples of the paper). A perpendicular line GO at an arbitrary point G of line AG determines the position of the center, O, of Mohr's circle. The two lines AC $\left(\text{slope } \frac{1}{n_1}\right)$ and AC′ $\left(\text{slope } \frac{1}{n_2}\right)$ determine vectors BC and B′C′ corresponding to the horizontal pressures σ_x. In their turn, vectors DE and D′E′ correspond to the vertical pressures, σ_y.

If C_1 is not equal to zero, the dam may be visualized as having a steeper slope $\frac{1}{n_0}$ and being at the "plastic" state under the action of the vertical body forces only. Let:

$$\sigma_x = n_0\,\tau_{xy} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (38)$$

from which, using Eq. 36*b*:

$$\tau_{xy} = \frac{C_1\,C_2}{n - n_0}\,(x - n\,y) \ldots\ldots\ldots\ldots\ldots\ldots (39a)$$

and

$$\sigma_x = \frac{n_0\,C_1\,C_2}{n - n_0}\,(x - n\,y) \ldots\ldots\ldots\ldots\ldots\ldots (39b)$$

Introducing the value of τ_{xy} from Eq. 39*a* into Eq. 36*a* and dividing Eq. 36*a*, thus modified, by Eq. 39*b*:

$$\frac{\sigma_y}{\sigma_x} = \frac{n - n_0 + C_1}{n\,n_0\,C_1} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (40)$$

Compute the values: $\frac{\text{DE}}{\text{BC}}$ and $\frac{n - n_0 + C_1}{n\,n_0\,C_1}$, in which n and C_1 are given, and $n_0 = \frac{\text{BC}}{\text{CF}}$, for various points C as in Fig. 11(*a*). Plot these values from points C outward, along the radii of Mohr's circle. The intersection of curves I and II thus obtained (Fig. 14) furnishes the true value of the ratio $\frac{\sigma_y}{\sigma_x}$. A simple trial-and-error procedure would also serve the same purpose.

It is easy to see that Eqs. 36 and 37 furnish the same results as Eqs. 21. In the case of a "plastic" region such as I or VII, in which $n = \infty$, the Rankine formula should be applied (Eqs. 22), and no special derivation is needed.

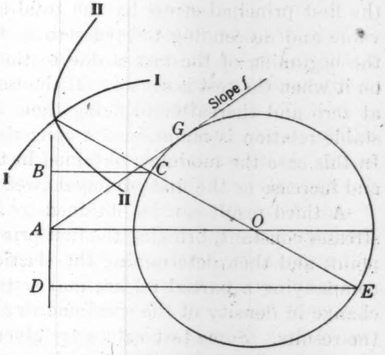

FIG. 14.—RATIO BETWEEN THE VERTICAL AND THE HORIZONTAL NORMAL STRESSES IN A "PLASTIC" REGION ($C_1 \gtrless 0$)

Stresses in "Elastic" Regions.—It is postulated in the paper that the material in the "elastic" regions obeys Hooke's law, which is not true. Afterward the condition of compatibility is used under the form of Eq. 3, which presumes that the material obeys Hooke's law. Using this condition, it is found that the stress distribution in "elastic" regions is rectilinear. This result is all that is needed for finding stresses in the "elastic" regions. As soon as the stresses at the boundaries of the plastic regions at a certain elevation are computed, the stresses in the "elastic" regions at the same elevation may be found simply by tracing straight lines as in Figs. 4 and 5, since equality (not "continuity" as the authors state) of stress across a boundary is postulated. Under the circumstances, it would be much simpler to postulate, directly, the rectilinear stress distribution in the "elastic" regions.

Slip Lines.—Instead of using Eqs. 24 and 25, the slip lines in a boundaryless "plastic" region may be located simply from Mohr's circle (Fig. 11). The major principal stress, σ_1, makes half the angle F′OE with the vertical. The two systems of slip lines make the angle $45° - \frac{1}{2}$ arc tan f with the direction of the major principal stress, σ_1, on both sides of it.

Title of the Paper.—The writer believes that the title of the paper is inappropriate. It is very questionable whether this method can be applied in the case of embankments made of a material different from the foundation, especially on a transverse slippery slope. Such is the case of many highway and railway embankments, dikes, and levees.

Conclusion.—In the opinion of the writer, the method described in this paper is interesting and original. Unfortunately, the method in question, although simple in itself, has been developed and presented in such a manner that quite a screen of mathematical symbols obscures its physical significance.

R. E. GLOVER,[14] ESQ., AND F. E. CORNWELL,[15] ESQ.—Professor Hennes objects to the use of Hooke's law for the material in the elastic zones, and quotes test results in support of his objection. The type of stress-strain relation expressed in Eq. 30 is obtained in a triaxial test when the second and third principal stresses are held constant and the first principal stress is raised progressively until failure occurs. The elastic modulus obtained by dividing the first principal stress by the total strain is variable, beginning at a finite value and descending toward zero as the test proceeds. The finite value at the beginning of the test is due to the initial pressure which must be placed on it when the test is set up. If the test is performed by starting all pressures at zero and thereafter bringing them all up together, so that a definite and stable relation is maintained among them, a different result will be obtained. In this case the modulus, obtained in the manner described, will start at zero and increase as the first principal stress increases.

A third result can be obtained by holding the second and third principal stresses constant, bringing the first principal stress about halfway to the failure point, and then determining the elastic modulus by observing the strains accompanying a partial release and restoration of the first principal stress. A change in density of the specimen due to a different packing will also modify the results. Some test values are given in Table 4.

In view of these differences it would appear that a closer approximation to the actual stress-strain relation than the simple one used by the authors could be chosen only after a careful study of the material, the proposed method of placing it in the dam, and the loads to be placed on it thereafter.

In connection with Figs. 8 and 9, Mr. Benscoter presents a discussion that appears reasonable for a granular mass with cohesion. The horizontal direct stress at a point in Fig. 8 corresponding to point A, Fig. 9, although not a principal stress, is only slightly greater than a fourth of the vertical stress. Similarly, for point B, slightly below the surface, the direct stress parallel to the downstream slope is almost twice that perpendicular to the slope, although these stresses are not the principal ones. As he states, Fig. 9 corresponds to non-linear solutions, whereas Fig. 8 was for linear ones.

[a] Computed by dividing the stress by the total linear strain. The linear strain is computed by dividing the volume strain by 3. [b] Computed by dividing the deviator stress by the total axial strain after the start of the test.

Good agreement was found between predicted failure at the reentrant corner common to regions V, VI, and VII and actual performance of several models, when instability was caused by raising percolation gradients in region VII. These tests are discussed further herein under remarks on Professor Hrennikoff's discussion.

The writers agree with Mr. Benscoter that the application of mathematical theory to soil analysis problems is behind similar practice in other fields, and they look forward to further development. They also agree that new methods for measuring pressures in embankments are needed urgently.

Professor Hrennikoff comments at some length on the uniqueness of the solutions and concludes that the proposed solutions are unacceptable unless some additional proof of their reasonableness can be supplied. To support his conclusion he describes procedures by which he attempts to show that a wide variety of stress states could be installed in the dam by some artificial conditioning of the soil mass. The writers object to his demonstration on the following grounds: The passive, plastic-state, stress distribution requires the presence of shearing stresses on horizontal and vertical planes, and therefore it would be impossible to set up such a state by using a smooth wall in the manner he describes. This statement is true also for the active, plastic-state, stress distribution and all the possible intervening elastic states so long as the boundary slope is not horizontal. A similar difficulty will be encountered if the wall is to be made rough. In this case, any of the foregoing stress states could be set up because the shearing stresses required on the vertical planes could now be maintained; but it would not be possible to eliminate the central gap without altering the shearing stresses because a removal of the walls would leave a discontinuity in the shear stresses along the plane of symmetry. This discontinuity represents a major violation of the requirement for equilibrium. If an elastic zone is introduced, these difficulties can be removed and the shear stress can be made to pass through zero at the plane of symmetry, as it should.

These difficulties with Professor Hrennikoff's demonstration are considered to be sufficiently serious to warrant a reconsideration of the adverse criticisms in his section 1. In the latter part of this section he objects to the use of plastic states in zones III and V of Fig. 4 and expresses a preference for an elastic state throughout for slopes as low as those shown. In reply to this objection it can be stated that a solution satisfying the elastic equations, and free from the aforementioned difficulties, will require the existence of stresses along the boundaries and these cannot be sustained by a cohesionless material. The active state was chosen for regions I and VII for the examples in Figs. 4 and 5 because it was considered to be the state which probably would exist in a granular mass that had been deposited by running water, as would be the case with many stream beds.

Having disposed of these details, a consideration of the question of uniqueness may be resumed. Professor Hrennikoff is correct when he states that the solutions are not unique. The writers would like to urge, however, that the difficulty is not due to the form of their proposed solutions but is inherent in the nature of the problem. This may be illustrated by the retaining wall problem. Here the active and passive states represent limiting states beyond which stress distributions of the linear type cannot exist. Between these limits, however, there are a multitude of elastic states possible, and it should be noted that all of them, including the active and passive cases, are solutions of the differential equations (Eqs. 3 and 12) which meet the boundary conditions. This does not include all the possibilities, since additional solutions of non-linear type probably can exist also. It is evident, then, that Rankine's active state solution for the case of no surcharge, for example, is not unique in the sense that this distribution must exist to the exclusion of all others. It remains a physical possibility, however, in spite of the fact that tests and experience show that greater horizontal pressures can exist. In practice, other factors besides the satisfaction of the differential equation and the boundary conditions must be taken into account when a decision must be made as to the design pressure of a retaining wall. These factors will include a consideration of the manner of placing the backfill and the conditions of service after completion.

It is necessary, also, to exercise an intelligent choice when selecting the stress states for the plastic zones in a dam. An active state for the downstream slope might be reasonable for a dam that is to be constructed by rolled-fill methods, whereas a hydraulic fill dam might require a different choice. These remarks will apply to the comments in Professor Hrennikoff's sections 1 and 4. The questions raised in section 3, regarding the use of Hooke's law, have already been dealt with in connection with Professor Hennes' discussion.

In regard to the question raised by Professor Hrennikoff in section 5, concerning continuity of stress, it may be stated that the choice here was a matter of judgment. In the case of a dam subjected to a changing load, where the boundaries between elastic and plastic zones must move, it was considered that a discontinuity of the normal stress parallel to the boundary would lead to difficulties in regard to compatibility of strains on the elastic side of the boundary in the case where this zone is widening. In other cases, a choice of equality for shear stresses along the boundary and for direct stresses normal to it seems to be indicated. In Fig. 5, if the percolation pressure gradients in zone VII are raised a certain amount, the elastic zone VI will collapse to a simple boundary, subjected to such a stress condition. In Example 2, the percolation pressure portion is incomplete, as was stated in the original description. This is due to the limitations imposed by the available solutions. In this case, the choice of a percolation pressure was made so that the actual body forces would be represented as well as possible. To determine how seriously the validity of the solutions would be affected by these limitations, some tests were conducted on model dams. These were built in a special tank which was about 20 ft long, 4 ft deep, and 3 ft wide. The model dams were approximately 2 ft high and rested on a foundation about 2 ft deep. The case shown in Fig. 6(*c*) was tested on several occasions with a dam whose upstream and downstream slopes were 1 on 3 and 1 on 2, respectively. The computations indicated that a sliding failure should occur at the downstream toe, with an upward percolation pressure gradient in zone VII, which would be slightly less than that required to cause piping. The exact figures for one of the models tested were 113.25 and 123.10 lb per sq ft per ft to cause sliding and piping, respectively. The sliding failure was observed to take place at the expected gradient and before any material had been removed by piping. The estimated gradient to cause piping was later confirmed very closely. It was concluded from this test that the neglected portions of the percolation pressure pattern did not influence the results of the computations greatly.

It is only necessary to test one point inside an elastic region if the equality is satisfied at the two boundaries. The reason for this may be stated as follows: The equation for R_0 is second degree in x for any constant value of y (say y_1) when linear stresses and a uniform coefficient of friction are assumed. A plot of this equation will show intercepts on the x-axis at both $x_1 = \beta_i\, y_1$ and $x_2 = \alpha_i\, y_1$ when plastic regions bound the elastic zone along $x = \beta_i\, y$ and $x = \alpha_i\, y$. Therefore, to check this inequality, the condition $R > 0$ at only one point along the line between (x_1,y_1) and (x_2,y_1) is sufficient. The same reasoning would apply for any other constant value of y, such as y_2, y_3, etc.; therefore, to check the inequality at only one point within the entire region is sufficient.

Tables 1 and 2 of Appendix II were worked out by restricting solutions of Eq. 18 to real values so that stresses as given by Eqs. 21 would be real. The discriminant was set equal to zero, and values of n were determined for the various weights, coefficients of friction, etc., shown in the tables. The two systems of percolation pressure contours used are shown in Figs. 6(*a*) and 6(*b*). Table 3 was computed by determining the percolation pressure gradient in zone VII which would cause this zone to assume the passive state. For somewhat lesser gradients, zone VI is absent and zone VII is in the elastic state, as explained previously.

Professor Krynine presents a summary of present methods of analysis of earth structures, which he follows with a brief geometrical interpretation of conditions in the plastic regions. This latter interpretation, together with his explanations of some of the mathematics, should prove helpful to any one going through the method for the first time. His section showing that differential equations are not necessary in plastic regions is an interesting presentation but would not shorten the computations for such regions. It was postulated that the material in the elastic regions obeys Hooke's law, but this assumption need not be made if a more reasonable behavior can be stated. Whether Hooke's law is postulated, or rectilinear stress in the elastic region is assumed, makes no difference, of course, when the designer is limiting himself to linear solutions, but as stated in the conclusion to the paper a general method of approach was being developed. The procedure as used in the paper would hold even if neither Hooke's law nor rectilinear stress were assumed.

In closing, the writers wish to take this opportunity to express their sincere thanks to those who have contributed to the discussions.

DRAINAGE OF LEVEED AREAS IN MOUNTAINOUS VALLEYS

BY GORDON R. WILLIAMS,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. MERRILL BERNARD, L. K. SHERMAN, C. O. CLARK, W. W. HORNER, WALTER T. WILSON, W. B. LANGBEIN, AND GORDON R. WILLIAMS.

SYNOPSIS

Various methods of disposing of the drainage from streams tributary to leveed areas are outlined in this paper. Brief consideration is given to the characteristics of these methods in fulfilling the design criterion that local drainage must be disposed of without causing damage appreciably greater than if the streams could flow unobstructed to the main river at low stage.

The details of a method of analyzing local hydrology and developing capacities of drainage structures under various conditions are presented. Graphs show volumes and rates of rainfall and runoff used in the design storms and floods, and relations between selected capacities and available storage for numerous designs for drainage structures.

INTRODUCTION

The drainage of leveed areas on the flood plains of deep valleys results in more problems, and fortunately more possible solutions to those problems, than does the drainage of other types of leveed areas. For example, in providing for local drainage of areas behind levees in the lower Mississippi River Valley, in general there is no alternative but to install pumping stations, as there is no opportunity for providing head or storage for other types of works. Also, the drainage of an urban area in relatively low country already provided with a storm-water drainage system can be disposed of only by a pumping station directly connected to the outfalls.

The problems of levee protection and subsequent local drainage in a mountainous valley may differ from those in level or rolling country in the following respects:

NOTE.—Published in January, 1942, *Proceedings*.

[1] Hydr. Engr., U. S. Engr. Dept., Wilkes-Barre, Pa.

(1) Levee protection is usually justified only for urban areas, in which case right-of-way costs will be high;

(2) The narrowness of the flood plain and the concentration of buildings limit the space for, and type of, structures to be built;

(3) The topography increases the drainage area tributary to the leveed area; and

(4) The topography requires that drainage be provided for streams whose hydrologic characteristics may differ from those of the protected areas.

Conditions (1) to (4) have been encountered in connection with flood-protection projects on the North and West branches of the Susquehanna River in Pennsylvania at the communities of Wilkes-Barre, Hanover Township, Kingston, Edwardsville, Plymouth, and Williamsport. The hydrologic procedures to be presented in this paper were developed particularly for the design of the protective works at Hanover Township, Plymouth, and Williamsport.

Local Drainage Requirements

Authorized projects of the U. S. Engineer Department for the protection of communities specify the river against which protection is to be provided. The degree of protection afforded against the specified river is based on studies of past floods and economic considerations. The adopted project usually provides for a substantial freeboard against the confined flow of the greatest known flood. A corresponding degree of protection is not required against flows from tributaries that pass through leveed areas, but it is required that the protective works on the main river shall not aggravate conditions caused by floods on the tributary streams. If a community desires flood protection from a tributary stream, or any other local improvements not a part of an authorized project, it must obtain authorization from Congress, which in turn may request the U. S. Engineer Department to make additional investigations for such improvements. Flood protection from small tributaries is very rarely justified.

The problem of preventing conditions within the leveed area from being no worse than if the tributary stream could flow unobstructed to the river is a difficult one and requires the consideration of a variety of situations. It is obvious from a hydraulic standpoint that a perfect solution is not possible, but from a damage standpoint a satisfactory solution can be obtained. In other words, it is possible to dispose of interior runoff at a rate that will prevent local damage from being appreciably greater than with no levee and the river at low stage. Benefits resulting from the fact that the main river has been prevented from entering the leveed area do not affect the economics of the local drainage problem because the elimination of main river damage has already been considered in determining the justification for the entire project.

There are two conditions for which the effect of floods on local tributaries must be considered:

(*a*) When the main river is at low stage and normal drainage to the river can take place; and

(*b*) When the river is at or above flood stage and special drainage works must be provided.

On the North Branch of the Susquehanna River conditions (*a*) and (*b*) are largely confined to well-defined seasons and therefore require a detailed study of probable hydrologic conditions that are characteristics of those seasons.

METHODS OF DISPOSING OF LOCAL DRAINAGE

There are six basic methods of disposing of local drainage from tributaries passing through leveed areas. These methods are: (1) Levees or walls along the tributary stream, (2) culvert with floodgate, (3) pressure conduit, (4) diversion channel, (5) storage reservoir, and (6) pumping station. Any of these methods may be used alone, but two or more are customarily used in combination. The selection of any method or combination of methods is based on studies of comparative costs and consideration of special local conditions.

(*1*) *Levees or Walls Along the Tributary Stream.*—From the standpoint of simplicity this method is to be preferred. However, it may be relatively costly for small tributaries or those with a drainage area of less than about 50 sq miles. The levees or walls must be extended upstream along the banks of the tributary to high ground and must be at an elevation sufficient to provide freeboard under all reasonable combinations of coincident discharges at the outlet of the tributary. If the tributary flows through an urban area, right-of-way costs for levees or walls may be prohibitive. Some tributaries along the Susquehanna River enter the flood plain at right angles to the course of the main river and then flow parallel to the river, sometimes for several miles, before finally emptying into the river. Under such conditions levees along the banks of a tributary become a major project in themselves. Levees or walls may be constructed part way up a tributary to connect with other works, such as a pressure conduit or pumping station. Levees have been provided in the Susquehanna River projects only on Lycoming Creek at Williamsport, which has a drainage area of 269 sq miles, but they were considered for other tributaries much smaller in size.

(*2*) *Culvert with Floodgates.*—Relief culverts with floodgates are used for floods occurring when the river is at low stage. Floodgates will pass local drainage at any stage in the river, provided there is sufficient differential head resulting from ponding at the intake. The selected size of culvert depends upon the design inflow and the allowable ponding elevation at the entrance. The latter elevation is dependent on the damage that will result from ponding. Obviously it is impossible to eliminate all ponding at the levee and still obtain an effective head on the culverts. Where conditions require excessively large batteries of culverts, there may be justification for providing smaller openings in combination with a fuse plug in the levee that can be blown out if conditions warrant. Relief culverts and floodgates have been constructed or planned at every point of natural outlet at levees in the Susquehanna River projects.

(*3*) *Pressure Conduit.*—A pressure conduit may be used if there is sufficient head. The total energy head or difference in elevation between stage in the river and the energy elevation at the entrance must be sufficient to overcome losses in the conduit and to produce velocity of flow under various combinations of river stage and conduit discharge. To obtain the head it is usually necessary to place the entrance some distance from the main river, resulting in a reduction in the area diverted and an increase in the length of the conduit. Pressure conduits are most practicable where the flood plain is narrow so that the construction and right-of-way costs are at a minimum. Sometimes the conduit can be laid in the original stream channel, but if that channel has been used as an outlet for storm-water drains, a separate intercepting sewer must be built or connections with gates or valves provided in the conduit. Pressure conduits also require supplementary works consisting of a pumping station and a relief culvert. The pumping station is required to dispose of runoff from the undiverted area and runoff from the diverted area in excess of the capacity of the conduit. The latter runoff will usually occur during low stages in the river and will pass through the relief culverts. The only pressure conduit under construction in the Susquehanna River flood-control projects is on Toby Creek at Kingston, but others have been considered.

(*4*) *Diversion Channel.*—Diversion of tributary streams to a point outside of leveed areas is usually practicable only when a stream is close to the limits of the protected area. In such cases changing the natural course of a tributary is often the most economical procedure. However, if the fall from the point of diversion to the river is great, and if there are highways and railroad tracks to be crossed, the costs of drop structures and bridges may indicate that some other method is more economical. Diversion channels have been planned for Coal Creek at Plymouth (diverted area, 1.6 sq miles) and Millers Run at Williamsport (diverted area, 7.8 sq miles).

(*5*) *Storage Reservoirs.*—Under certain combinations of favorable conditions it may be economical to construct storage reservoirs to impound the runoff of tributaries during floods in the main river. Reservoirs may be located at levees or at higher elevations farther upstream. In order to satisfy the criterion adopted for the design of local drainage structures, the reservoir need not provide flood control during low stages in the main river and hence has only to provide storage for the limited period in which the relief culverts cannot operate. Such reservoirs may be effective with only 2 or 3 in. of storage instead of the 6 in. usually considered necessary for flood control. Reservoirs with dams must be constructed back in the hills where dam sites are available, in which case there usually will be a considerable uncontrolled area, the runoff from which must be pumped. In addition, the usual relief culverts must be provided for floods not controlled by the reservoir. Reservoirs with dams have been considered but never found to have been justified in the solution of levee drainage problems in the Susquehanna River Basin; but reservoirs adjacent to levees have played an important part in the solution of such problems.

(*6*) *Pumping Station.*—If the hydrographs for design floods are routed through existing ponding areas and constrictions in the channel and valley of a tributary stream, it often will be found that, with only a relatively small rate of outflow, water-surface elevations can be kept close to conditions prior to the construction of the levee. Hence, a pumping station is used more than any other method to satisfy the drainage criterion. Such pumping installations usually take full advantage of the modifying effect of available storage adjacent to the levee. Such storage is usually in low marginal areas where development has been limited and where damage will be slight. The chance that such areas may be developed and filled after the levee is built must be considered and requires an appraisal of possible future development. Relief culverts must be provided in connection with pumping stations to dispose of runoff that may occur when the river is at low stage. A total of eleven pumping stations is planned, for unsewered or partly sewered areas on Susquehanna River levee projects in Pennsylvania. An additional eleven pumping stations are planned for completely sewered areas.

LOCAL HYDROLOGY

The determination of appropriate rates and volumes of runoff to be used in the determination of the capacities of drainage structures is exceedingly difficult, especially when there are no available records in the immediate vicinity of a project. It requires a consideration of the seasons in which different conditions may occur, an analysis of rainfall and runoff characteristics of these seasons, and a determination of the runoff characteristics of each sub-area to be drained. In usual storm-water drain design it is considered necessary only to determine peak rates of runoff, and the effect of storage is neglected. In the design of drainage structures for natural areas behind levees, it is necessary to route complete hydrographs through existing and proposed ponding areas in order to determine the modified peak rates for which to provide. The hydrologic problem is to determine, as well as to route, hydrographs that have a reasonable probability of occurrence under different conditions.

Basic Data.—It is desirable to have actual records or estimates of stage in the main river, of runoff from the tributaries, and of local rainfall and snowfall. If the main stream is important as is the Susquehanna River, long records of stage are usually available or can be determined from near-by places by means of gage-relation curves. Continuous records of stage on the North Branch at Wilkes-Barre began in 1896 and on the West Branch at Williamsport in 1895.

The tributary creeks, on the other hand, are small and have been considered too unimportant to be gaged. On some there are a few flood marks that make it possible to estimate the maximum floods known to the residents. For the most part there are no records on which to base times of concentration or unit-hydrograph characteristics.

Rainfall records at nonrecording gages are available at many places in the Susquehanna River Basin, and some of the records have been kept for 45 years or more. Unfortunately, there are only two recording gages in the basin in Pennsylvania upon which to determine the frequency of rainfall intensities of short durations. These gages are located at Harrisburg and Scranton. All these records have been analyzed and form the initial basis for determining the capacity of drainage structures.

In order to obtain more reliable data on the runoff characteristics of the small drainage areas adjacent to active or proposed flood-control projects, the

U. S. Engineer Department has established, in cooperation with the U. S. Geological Survey, a number of gaging stations on small areas. The smallest areas on which gaging stations were established are listed in Table 1.

TABLE 1.—GAGING STATIONS ON SMALL AREAS IN THE SUSQUEHANNA RIVER BASIN IN PENNSYLVANIA

No.	Stream	Place	Area[a]
1	Paxton Brook	Harrisburg	11.2
2	Solomon Creek	Wilkes-Barre	15.4
3	Hageman Run	South Williamsport	6.3
4	Grafius Run	Williamsport	3.1

[a] Drainage area in square miles.

A recording rain gage was also established on the headwaters of Solomon Creek. The new system of recording rain gages established by the Federal State Flood Forecasting Service of Pennsylvania is proving of increasing value in connection with newly established stream gaging stations. These streamflow and rainfall gages, even when in operation for only one flood season, often give information that results in the saving of large sums of money in the design of drainage structures.

Flood Season.—The flood season on the Susquehanna River was determined from an analysis of stage records at Wilkes-Barre. The number of flood peaks in the record above damage stage are as follows:

Month	No.	Month	No.
October	3	April	6
November	3	May	1
December	1	June	0
January	3	July	2
February	4	August	0
March	13	September	0

It is evident that 83% of the peak damage stages have occurred in the season from November to April, inclusive, and that March and April are the most severe flood months. The purpose of defining the flood season is to determine when the drainage structures will be used and what rainfall and runoff conditions can be expected during the period of use. Runoff from snow cover can be expected throughout the selected season. If the season had been extended farther to include October and May, the absence of snow runoff and the increased losses from infiltration would counteract the higher rainfall rates to be expected during those months.

Rainfall in Flood Season.—It should be emphasized that the drainage areas under consideration are so small that point rainfall data are sufficient for winter storms and lead to a desirable factor of safety for summer storms, and that area-depth relations need not be introduced to add to the complexity of the problem. A study was made first of 1-day and 2-day peak rainfalls in the flood season for eighteen stations in northeastern Pennsylvania. The excessive rainfalls were tabulated by months and then combined into a seasonal record. The frequency of the various rainfall depths was computed and plotted and mean curves drawn. A summary of the results is shown in Table 2.

Considering that the rainfall depths were obtained from calendar-day records of rainfall, and that the actual durations of the rainfalls probably varied over a wide range, there is a remarkable correlation between the results. This is due in part to the fact that winter storms cover wide areas and cause a relatively uniform distribution of precipitation. Such a correlation, which has been anticipated by other investigators,[2] should not be misconstrued as indicating a high degree of accuracy in the frequency-depth relations. Some other period of record might show a similar correlation but not the same frequency-depth relations.

TABLE 2.—SUMMARY OF RAINFALL RECORDS FOR THE SEASON, NOVEMBER TO APRIL, INCLUSIVE

Station (Pennsylvania)	Elevation, in ft above mean sea level	Length of record, in years	Rainfall, in Inches[a]					
			5 Years		10 Years		15 Years	
			1-day	2-day	1-day	2-day	1-day	2-day

[a] Rainfall to be equaled or exceeded once in the period indicated. [b] On divide between Susquehanna River and Delaware River basins.

Because the critical rainfalls on small areas are those of high intensity and short duration, records of calendar-day rainfall have little application except where extensive flood storage is planned. It is believed, however, that these rainfalls can be used as an index of the possible regional variations in rainfalls of shorter durations. Furthermore, the data in Table 2 indicate that, for the winter season, the increase in depth of rainfall with decrease in frequency is relatively small. For example, the average increase in the expected depth of rainfall between the 5-yr and 10-yr frequencies or between the 10-yr and 15-yr frequencies is only about 10%. This characteristic of the winter storms is significant in the design of drainage structures and indicates that the degree of protection against interior flooding can be increased often without a large increase in expenditure.

---

[2] "The Reliability of Rainfall Intensity-Frequency Determinations," by C. W. Thornthwaite, *Transactions*, Am. Geophysical Union, Pt. II, 1937, pp. 476–484.

In order to obtain data on the winter rainfalls of short duration, the original charts for the recording gages at Scranton and Harrisburg were studied. All peak rainfall depths for durations of from 5 min to 12 hr were determined. The rainfall depths for each duration were arranged in order of magnitude, and the frequency with which each value was equaled or exceeded was computed and mean curves drawn. Frequency curves for the Scranton record, which differ but little from those obtained from the Harrisburg record, are shown in Fig. 1. Total depths of rainfall, instead of hourly rates, were used because they can be applied directly to unit hydrographs and because depth-frequency curves when plotted on semilogarithmic paper indicate straight-line relations.

The computed frequencies for the rainfalls of all durations, including the 1-day and 2-day rainfalls, were determined by the formula

$$f = \frac{2\,N}{2\,m - 1} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which N = length of record in years; m = serial number of each item, when items are arranged in descending order of magnitude; and f = frequency, in years, with which any item will be equaled or exceeded. Eq. 1, which is based on the theory of least squares, has been universally accepted in estimating flood-peak frequencies but has been rarely used in determining rainfall frequencies. No doubt the reason is that rainfall records furnish more items for analysis, and investigators have considered that theoretical adjustments to available records were not necessary. The formula is just as applicable to one type of frequency analysis as it is to another, including the construction of duration curves.[3]

Design Storm for Flood Season.—In selecting a design storm there are two possible courses of procedure. One is to use the actual rainfalls from some severe storm of record in the flood season, and the other is to derive a synthetic storm from rainfalls of equal frequency. The first method may result in either under-design or over-design of drainage structures unless the characteristics of the design storm are compared carefully with many other storms, particularly those that have occurred during high stages in the main river. The second method, which was chosen for use in the Susquehanna Basin, results in a storm that is rarer than the indicated frequencies of the component rainfalls but eliminates to a large extent the uncertainties resulting from the use of a particular storm. This procedure has been suggested by other engineers.[4,5]

An examination of the rainfall depths in Table 2 indicated that the studies of the recording gage record at Scranton could be applied to areas in the vicinity of Wilkes-Barre. In applying the same studies to areas in the vicinity of Williamsport, the rainfalls of short duration were increased by the ratio between the Williamsport and the Scranton daily rainfalls of the same frequency.

[3] "Duration Curves," by H. Alden Foster, *Transactions*, Am. Soc. C. E., Vol. 99 (1934), pp. 1213–1267.

[4] Discussion by Merrill M. Bernard of "Relation Between Rainfall and Run-Off from Small Urban Area," by W. W. Horner and F. L. Flynt, *ibid.*, Vol. 101 (1936), p. 189.

[5] "Storage Basins as a Supplement to Storm Sewer Capacity," by John A. Rousculp, *Civil Engineering*, November, 1940, pp. 715–718.

The design storms were derived by combining rainfalls of equal frequency

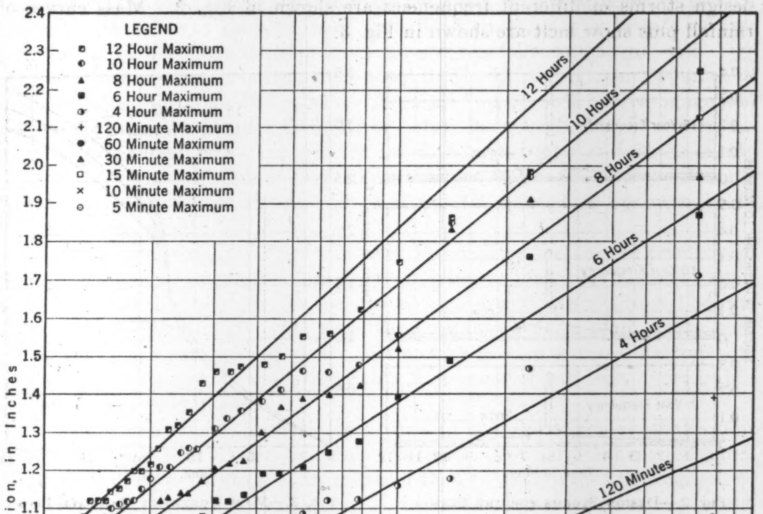

FIG. 1.—FREQUENCY ANALYSIS OF PRECIPITATION AT SCRANTON, PA., FOR THE SEASON NOVEMBER TO APRIL, INCLUSIVE

into a histogram which was nearly symmetrical and which had the maximum intensity at the midpoint. As 10-min unit hydrographs were used for areas less than about 8 sq miles, rainfalls in the design storms were computed for

10-min intervals. In northern Pennsylvania it was assumed that there would be 100% runoff in the winter season and that, in addition, there would be runoff from melting snow at the rate of 1 in. in 24 hr. The histograms for the design storms of different frequencies are shown in Fig. 2. Mass curves of rainfall plus snow melt are shown in Fig. 3.

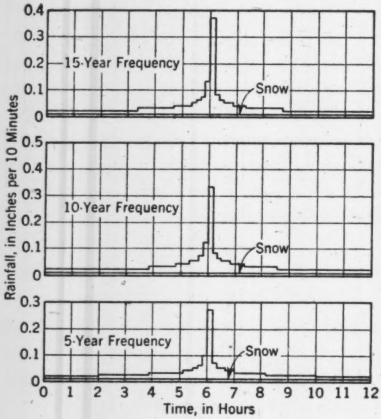

FIG. 2.—DESIGN STORMS FOR THE SEASON NOVEMBER TO APRIL, INCLUSIVE

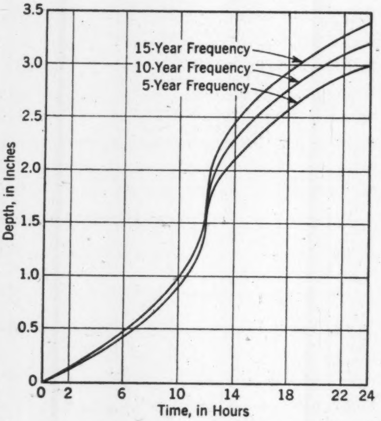

FIG. 3.—MASS CURVES OF RAINFALL PLUS SNOW MELT FOR DESIGN STORMS

At this point it is well to raise the question as to whether the design storm should be based on all rainfalls in the flood season or on rainfalls that have occurred coincidental with flood stage in the main river. Theoretically the latter rainfalls should be used, but practically they do not form a reliable basis for design in the locality under consideration. Using available records of daily rainfall it was found, for example, that the 10-yr, 1-day rainfall for the entire flood season was equaled or exceeded about once in 35 or 40 years in coincidence with high stage in the river. A similar study was conducted taking the hourly rainfalls at Scranton that occurred during high stage at Wilkes-Barre. The results were not conclusive and no reliable frequency curve could be drawn. It was noted, however, that many intense hourly rainfalls did coincide with high stage in the river. In order to determine frequencies of rainfalls coincident with high river stages, which would be as reliable as the frequencies of rainfall throughout the entire flood season, it would be necessary to have a record of coincident events three or four times as long as the available rainfall record. It should also be emphasized that winter floods on the river and on the small tributaries do not have independent meteorological causes. The winter storm is widespread and is usually accompanied by warm temperatures that cause melting of snow throughout the storm area. Peaks of floods on the tributary streams will rarely coincide with peaks on the main stream, but tributary peaks will often coincide with high stages on the main stream. Furthermore, the phenomenon of two or more storms in succession is a common occurrence in the Susquehanna Basin, as in March, 1936. In the flood of March-April, 1940, there were three distinct flood rises above the damage stage at Wilkes-Barre in a period of 12 days.

On rivers with drainage areas in excess of about 10,000 sq miles, or smaller rivers that take many days to reach their flood crests, it may be safe to base the design of drainage structures on known rainfalls coincident with high stages. Such studies have been conducted by the U. S. Engineer Department for cities along the Ohio River, where there are long records of river stage and coincident rainfall. On the Ohio River below Pittsburgh, Pa., it can be assumed safely that there is no relation between local runoff and floods on the main river. The duration of high stages is much longer than on the Susquehanna River at Wilkes-Barre, and therefore there is more opportunity to record coincident rainfall.

Design Hydrograph for Flood Season.—Flood flows that would result from the design storms were determined by applying rainfall plus assumed snow melt to the unit hydrographs for the various local areas. As mentioned before, the entire storm rainfalls were considered to represent rainfall excess, and infiltration was assumed to be zero. The unit hydrographs were obtained from actual records of runoff where available, but most of the unit hydrographs were derived synthetically.

Unit Hydrograph.—The basic procedure in determining a synthetic unit hydrograph was first to derive a unit hydrograph for a rainfall period equal to the time of concentration of an area and then to modify that hydrograph so that it was applicable to the rainfall period used in the design storm, which was 10 min for most areas. The basic theory involved has received consideration elsewhere.[6]

Determination of the time of concentration was a problem in itself. A procedure developed by Z. P. Kirpich,[7] Jun. Am. Soc. C. E., was used. Briefly, this method is to compute, for areas with known times of concentration, correlation factors based on length of stream channel, slope of channel, and average slope of basin. These factors are plotted against known times of concentration, and the resulting curve is used to determine times for other areas where only the correlation factor is known. The results from the data plotted by Mr. Kirpich were extrapolated to give a basis for determinations applicable to the larger and more mountainous areas in the Susquehanna Basin. The extrapolation was checked closely from field data obtained from one mountainous area of about 15 sq miles. It is realized that no results of great precision are obtained by such a procedure. However, it should be more reliable than mere guessing at velocities of overland and stream-channel flow. Furthermore, when more field data become available, it is believed that extension of the same procedure will yield results of greater precision.

The peak discharge of the unit hydrograph for a rainfall period equal to the time of concentration was determined by use of the principle that, if the rainfall excess continues for a period equal to the time of concentration, the rate of runoff will equal the rate of rainfall excess. The familiar rational formula

---

[6] "Analysis of Run-Off Characteristics," by Otto H. Meyer, *Transactions*, Am. Soc. C. E., Vol. 105 (1940), pp. 83–141.

[7] *Civil Engineering*, June, 1940, p. 362.

$$Q = C\,i\,A \quad \text{.......................} \quad (2)$$

is based on this theory. If C, the runoff coefficient, is considered equal to unity, the formula can be considered to represent rainfall excess. As the unit hydrograph represents 1 in. of runoff from a uniform rainfall, the rate of rainfall excess equals

$$i = \frac{1}{T_c} \quad \text{.......................} \quad (3)$$

in which T_c equals the time of concentration in hours. As T_c for small areas is usually expressed in minutes, i equals $\frac{60.}{T_c}$ The area, A, is expressed in acres, and the peak rate of discharge, Q_p, for the unit hydrograph is expressed by the formula

$$Q_p = \frac{60\,A}{T_c} \quad \text{.......................} \quad (4)$$

The writer believes that this theoretical rate of discharge is never reached in the time T_c for natural areas having appreciable channel and depression storage. However, such an assumption is conservative and must be used until future studies indicate how the storage effect can be evaluated.

To estimate the shape of rising and falling limbs of the synthetic unit hydrograph, contours representing equal times of travel to the outlet were drawn. From these contours a time-area graph was constructed, and the ordinates to the unit hydrograph were made proportional to this graph. Of course, the use of time contours and time-area graphs is not new, but the relation between those principles and that of the unit graph appears to have been first demonstrated by Merrill Bernard,[8] M. Am. Soc. C. E., and later developed by others,[6] who introduced the unit hydrograph for the time of concentration. In order to conform more nearly to natural unit hydrographs, the falling limbs were arbitrarily flattened so that the time from the peak to zero flow was equal to $\frac{3}{2}\,T_c$. Typical unit hydrographs for an area with a time concentration of 33 min are shown in Fig. 4.

---

[8] "An Approach to Determinate Stream Flow," by Merrill Bernard, *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 349.

Maximum Probable Storm and Flood.—In order to provide adequate relief openings when the main river is at low stage, a maximum probable storm and flood were computed for each area. The maximum probable storm would be of the summer cloudburst type. The rainfalls for such a storm were determined from an envelope of maximum known rainfalls for northeastern United States, which has been published previously.[9] Using this curve a synthetic storm was constructed in the same manner as the winter design storm. The maximum probable flood hydrograph was derived by deducting an estimated infiltration loss from the rainfalls and then applying the net depths to the unit hydrographs. Studies of storms on larger areas where stream-flow records were available indicated that an infiltration rate of 0.3 in. per hr was conservative for summer storms. This rate assumes that there has been antecedent rainfall, and much higher rates would prevail if the rain fell on dry ground.

No claim is made that the hydrologic analyses presented herein represent perfection in such studies, but rather that they represent a workable and reasonable solution to a difficult engineering problem. Further refinements probably could not be justified from the standpoint of the reliability of the available basic data and from the probable savings in the design of the structures.

DETERMINATION OF CAPACITY OF DRAINAGE WORKS

The hydrographs for the winter design flood and the maximum probable flood, determined as described in the previous section, were routed through all areas of appreciable existing and proposed storage. Most of the effective storage is found to be in the flood-plain areas. In the case of a proposed diversion channel or pressure conduit there is usually little or no storage above the entrance to modify the inflow hydrograph for the diverted area and to reduce the required capacity. On the other hand, structures such as pumping stations and relief culverts, which are located at levees, take full advantage of all modifying storage in the flood plain, which reduces the required capacity without violating the design criterion. Of course, the area drained is greatest at the levee, but the increase in the volumes of runoff is usually offset by the increase in ponding facilities.

It was considered reasonable for the drainage works to have a capacity sufficient to dispose of runoff from the 10-yr winter flood without causing damage in the flood plain appreciably greater than if water could flow freely to the river at low stage.

In order to determine the incremental increase in damage that would result from various ponding elevations at the levee, stage-damage curves were plotted for each area affected. Data for these curves were obtained from detailed surveys for the entire flood plain. The latter surveys had been made previously in order to determine the justification for each local protection project as a whole.

Because of the characteristics of the winter storms, already discussed in this paper, the selection of the rainfall frequency as between 5, 10, or 15 years usually does not have a very material effect on the size of drainage structures. The greater the flood-plain storage, the less the variations in inflow rates affect the capacity of structures. Fig 5 shows the relations between pumping capacity and storage for a number of designs based on 10-yr winter rainfalls. Local conditions affect the flood routing and in turn affect the selected pumping capacities, thus causing a rather wide dispersion of the plotted points. The pumping capacities required in terms of inches per day give rather large values, but it must be remembered that these capacities represent peak rates that are needed for only a few hours at a time.

---

[9] *Transactions*, Am. Soc. C. E., Vol. 106 (1941), Fig. 21, p. 1504.

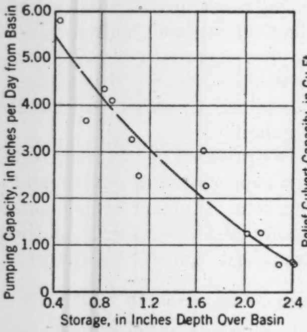

FIG. 5.—RELATION BETWEEN CAPACITY AND FLOOD-PLAIN STORAGE FOR VARIOUS PUMPING STATION DESIGNS

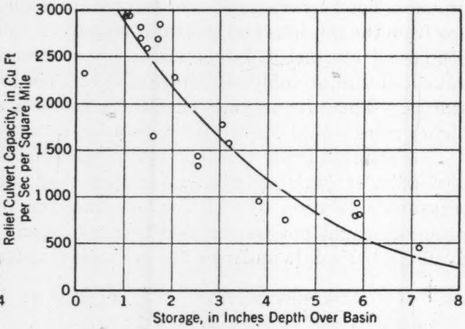

FIG. 6.—RELATION BETWEEN CAPACITY AND FLOOD-PLAIN STORAGE FOR VARIOUS RELIEF-CULVERT DESIGNS

The relations between relief-culvert capacity and flood-plain storage for a number of designs are shown in Fig. 6. In this case the inflow is that from the maximum probable flood. These relations are also greatly affected by channel and storage conditions in each individual basin.

It may appear to some that the basis of design for drainage structures presented herein is rather conservative, but it should be for the following reasons:

(*a*) Only a part of the present flood-plain storage is within the right of ways of the projects and hence is subject to reduction by filling in for future development;

(*b*) Future development may increase incremental damage resulting from ponding; and

(*c*) Future development may cause an increase in the volume and concentration of runoff.

ACKNOWLEDGMENTS

Flood-control work on the Susquehanna River in Pennsylvania has been conducted by the U. S. Engineer Office, at Baltimore, Md., under the following district engineers: Col. E. J. Dent and Col. F. C. Boggs, Members, Am. Soc. C. E., and Col. W. A. Johnson and Lt.-Col. H. L. Robb. E. W. Digges, Assoc. M. Am. Soc. C. E., is chief of the flood-control division. Acknowledgment for contributions to the studies described herein and for assistance in the preparation of this paper is made to Mr. Kirpich, to E. H. Bourquard, Jun. Am. Soc. C. E., and to many other members of the Baltimore Engineer Office. The opinions expressed herein are those of the writer and do not necessarily reflect the policies of the U. S. Engineer Department.

DISCUSSION

Merrill Bernard,[10] M. Am. Soc. C. E.—Although Mr. Williams has confined his discussion to projects created by the construction of levee systems of considerable magnitude and importance, similar situations of lesser extent are to be found in nearly all of the great metropolitan areas and in many smaller cities and towns. His paper is a contribution to the solution of these problems and should be an encouragement to those who would treat them rationally rather than empirically.

In planning for the disposal of tributary flow within leveed areas, the ideal situation to be met is that of a synchronization of flow which, by virtue of a consistently shorter concentration period, would insure the discharge of the lateral flow under positive head through automatic floodgates for all conditions of outside stage. These circumstances may be encountered on small watersheds as headwaters are approached, but are never sufficiently realized to preclude the necessity of resorting to other means of control discussed by the author. In addition to the six methods mentioned by him, opportunity might occasionally present itself to consider the use of a secondary levee provided with gates and pumps. Under reasonably favorable channel and surface slope conditions, liberal gate dimensions to insure maximum duration of flow under natural head, and minimum supplemental pumping, the effect would be to enhance the utilization of areas dedicated to temporary storage and to reduce the depth and duration of flooding on developed, contiguous, low-lying areas. The storage basin itself could be closed in without reducing its capacity by substituting depth created by the secondary levee for area covered by the unconfined basin. The sequence of operation would be: (1) Gravity flow through upper and lower gates, (2) lower gates closed with the reversal of head, (3) lower pumping started, (4) upper gates closed with reversal of head, (5) upper pumping started, (6) upper pumping stopped, and (7) lower pumping stopped.

The effect, on cost, of dividing the pumping installation into two units, the additional cost of constructing the secondary levee, and the greater operating cost, if any, would have to be weighed against the benefits of added protection in each particular case.

The author has capitalized reasonably on the fact that flooding in eastern Pennsylvania is confined to a rather definite "flood season." The 12-hr precipitation record at Harrisburg, Pa., demonstrates the differences between annual rainfall and that within the adopted flood season:

F	All storms or maximum yearly	All storms or maximum seasonal
2	2.0	1.5
5	2.7	1.8
10	3.5	2.0
40	5.0	2.4

The column headings indicate a confirmation of the author's opinion that the selection of the maximum yearly or seasonal values, when treated through

---

[10] Hydrologic Director, U. S. Weather Bureau, Washington, D. C.

Eq. 1, will produce the same frequency-depth relations as if all rainfall amounts within the record were considered, any differences being confined to frequencies of less than 2 years. Also, the differences in the values of the second and third columns represent reduction in design values gained by restricting the frequency series to the flood season. This in effect is offsetting the higher intensities of summer-type rainfall with the greater reductions for infiltration prevailing during the off-flood season. The frequency of the greater amounts occasioned by the inclusion of all storms within the record is reduced by increasing the value of *m* in the frequency equation.

The value of 1 in. in 24 hr for the contribution of melting snow to runoff seems somewhat low. There is little secure knowledge of this phenomenon but, on watersheds sufficiently small to allow snow-melt runoff from the entire area within a melting period, greater amounts could be expected. The average temperature for the locality that can occur with snow cover and coincidental rainfall could be as high as 55° F for a 24-hr period. The general opinion is that from 0.05 to 0.15 in. of snow-melt runoff per degree-day can be expected, depending upon the state of the snow mantle. Under these conditions runoff depth from 1.1 to 3.5 in. is possible. This does not include the contribution of free water present in a mantle of snow of low quality.

L. K. SHERMAN,[11] M. AM. SOC. C. E.—An interesting and logical analysis of the problem of local or interior drainage of leveed areas in mountainous valleys is presented in this paper. The author calls attention to the difference between conditions in the lower Mississippi River and the Susquehanna River valleys. Be that as it may, the conditions on the upper Mississippi and the Illinois rivers differ from those on the Susquehanna River in degree rather than in principles involved. Many of the levee districts are adjacent to steep bluffs extending to a height of from 200 to 600 ft. The runoff from the lateral streams is swift and flashy.

In either location, the first principle of design is the elimination, in so far as possible, of all of the hill water entering the leveed area. In the case of bottom lands to be used as agricultural drainage and levee districts, the upstream and downstream limits are generally confined to the distance between two lateral streams. Major lateral streams, through a town or between two adjacent drainage districts, must be carried direct to the river in a wide floodway and with levees of ample height at their junction with the bluffs or hills. Many levee districts were drowned out during the floods of the Illinois and Mississippi rivers in 1926–1927 due to overtopping of the lateral levees when there was ample freeboard along the main river. The Illinois and Mississippi rivers probably have a longer, higher stage period than do the rivers in Pennsylvania. The opportunity for the occurrence of peak lateral flow with fairly high river stages is not so great in Pennsylvania. Nevertheless, the additional insurance cost is so relatively small that the design of lateral levees should be predicated upon the synchronization of peak flow in both lateral and river channels. The writer would take exception to the author's remark under "Local Drainage Requirements": "A corresponding degree of protection is not required against flows from tributaries that pass through leveed areas."

---

[11] Cons. Engr., Chicago, Ill.

The author states (see heading "Methods of Disposing of Local Drainage: (1) Levees or Walls Along the Tributary Stream"): "Some tributaries along the Susquehanna * * * then flow parallel to the river, sometimes for several miles, before finally emptying into the river." This is also a common phenomenon on the Mississippi River. The flood profile of the lateral, at the upper end of the chute, is generally at a higher elevation than the main river across the dividing strip of land. In the case of the Fabius River, in Missouri, advantage of this situation was taken to dig a pilot channel cutoff across the strip between the Fabius and the Mississippi rivers. In less than two years, the floods of the Fabius had enlarged the cutoff to full size and had completely filled up the old stream channel, below the diversion, to a depth of 3 or 4 ft above ordinary low water. A serious menace and expense in levee maintenance were overcome by this simple expedient.

Without resort to excessive factors of safety, the author has presented a logical analysis of the rainfall-runoff problem for small tributary streams. Neglect to realize the importance of this problem, undoubtedly, is the reason for the numerous levee failures heretofore mentioned.

Fig. 4 may be a little puzzling to those who have become accustomed to using only the percentage distribution graph. The two hydrographs shown are true unit hydrographs. Each one represents the volume of 1 in. of runoff in specified times.

There appears to be little agreement on the definition of time of concentration. The writer defines it as the time period from the beginning of a uniform rate of rainfall on a basin until the runoff rate becomes a constant.

On this basis the writer tested the 33-min hydrograph in Fig. 4. Six average ordinates were scaled from the 10-min unit hydrograph. The summation process was applied to a series of 10-min net rains of 0.303 in. or a rate of 1.818 in. per hr. The average rate of runoff between 30 and 40 min was 940 cu ft per sec; checking a peak somewhat less than 1,000 cu ft per sec, the average between 40 and 50 min was 993 cu ft per sec and at 50 min the discharge was 1,000 cu ft per sec and continued thereafter at that rate as long as the uniform rain persisted.

This curve here developed by the writer is the "cumulative curve" introduced by Russell Morgan and D. W. Hullinghorst.[12]

A unit hydrograph, if available, reflects storage effect, and independent storage determination is not necessary; $T c$ is not an exact constant for a given basin. It varies with the condition of initial soil moisture and time of transit. The latter is governed by stage or rate of discharge. For all practical purposes, the author's derivation of $T c = 33$ min checks with the writer's definition of time of concentration.

The use of zero infiltration capacity is sound for most levee districts when the river stands against the levee. Many Illinois and upper Mississippi districts, with sandy substrata, show an actual inflow seepage of 0.25 in. or more per day. These same districts in July and August will have a large infiltration capacity.

---

[12] See "The Flood Hydrograph," by Howard M. Turner and Allen J. Burdoin, *Journal*, Boston Soc. of Civ. Engrs., July, 1941, discussion p. 272.

It is to be expected that the requisite pumping capacity for interior drainage should be greater for leveed municipalities than for leveed agricultural districts. Fig. 5 indicates an astounding difference. The experience of years has shown that a pumping capacity of 0.27 in. in 24 hr is adequate for all districts except those affected by continuous backwater from the river. In this case 0.50 in. in 24 hr is required.[13] A part of this difference is probably due to the availability of the interior ditches and low lying waste lands for storage, and a part is due to the fact that a material infiltration capacity exists during the season of possible crop damage.

C. O. CLARK,[14] JUN. AM. SOC. C. E.—The drainage of leveed areas in mountainous valleys is soundly analyzed by the author. The approach to the drainage problem by way of rainfall frequency, runoff, and the unit hydrograph has several important advantages over empirical design. First, it is well balanced, in that it is neither grossly inadequate, as when inapplicable empirical relations are applied, nor wastefully over-adequate, as when provision is made for some recent occurrence that is really phenomenal and very unlikely to recur. Second, the solution is approached from the over-adequate side, since cost forces a reduction of adopted size below the first calculation, with the result that, in the usually broad range of acceptable solutions, the more adequate are adopted. Third, the extreme cost of some of the first-calculated solutions leads to an ingenuity of solution not inspired by the approach from the inadequate side. Fourth, utilizing rainfall frequency data, the engineer usually comes to his answer with the deliberate knowledge that the provided capacity may be overtaxed, but that the payment of the damage will be cheaper than its prevention.

The possibilities for utilization of rainfall records coincident with flood stages present a promising opportunity for reduction of cost of pumping installations. The writer, in 1937, made for the U. S. Engineer Department the first studies along this line for the cities of Louisville, Ky., Evansville, Ind., and Cairo, Ill., along the Ohio River, where the procedure is unquestionably sound. The procedure can be utilized for drainage along streams which are so small that crests are reached in as little as 36 hr.

There are many circumstances in which the frequency of rainfalls that have occurred coincidently with flood stage in the main river can be used. Whereas rainfall during damaging flood stages may be too infrequent to study, rainfall during moderate and low stages is common enough to indicate the frequency with which it can be expected at high stages.

The writer believes that most of the floodtime rainfall may be treated as a phenomenon independent of the flood-producing rainfall, and he found this to be true in the following example. This depends, of course, upon the difference in time between flood peaks on the main stream and on the tributary. If the time difference is less than 24 to 36 hr, partial dependence is likely, since both floods might result from the same storm. In this case, however, drainage should be estimated for the flood-producing storm, rather than some other synthetic storm, as both together are unlikely.

---

[13] "Cost of Pumping for Drainage," by J. G. Sutton, *Technical Bulletin No. 327*, U. S. Dept. of Agriculture, October, 1932.

[14] Engr., U. S. Engr. Office, Winchester, Va.

If the time difference is more than 36 hr, independence of storm causes is essentially attained. Although general conditions are more favorable for rainfall than the average, and rainfall therefore might be more probable than average, the normal movement of storms in the Eastern United States is such that, 2 days after a severe storm, a region is quite likely to be in the high-pressure area, and to be relatively fair, with a reduced probability of rainfall.

However, it is not necessary to assume that the causes are strictly dependent or independent. The degree of dependency can be established. Thus, from the correlation of rainfall and low-river stages, it can be established that rainfall during flood stages is one, two, or several times as probable as average. This conclusion can be extended to higher stages. The probability of heavy rainfall is directly proportional to the total length of experience, almost any rainfall being probable in a long enough period of exposure. If, during a particular period of time, such as floodtime, rainfall were twice as probable as normal, the same rainfall could be expected in that period as in a normal period twice as long as that under consideration.

The duration of main-stream floods is very short (only a few days), so it may take a good many years to build up a year of exposure to floodtime rainfall. If pumping is necessary at the annual flood stage, and the average duration of floods above annual stage is 2 days each, the exposure of an area to floodtime rainfall during 50 years is only 100 days. If rainfall is twice as likely to occur, or two times as probable as normal, the exposure is equivalent to 200 days of normal exposure, and the rainfall to be expected is that which normally occurs once in 200 days.

To establish the relative probability of rainfall during floodtime, it is only necessary to establish a sufficiently low limit of river stage to include the desired number of rainfall occurrences. The probable normal experience for the floodtime period is computed for the same period of time as the aggregate period during which the river was above the critical stage, and is compared with the actual floodtime experience as plotted or computed in the manner suggested by the author. If the computed and observed frequencies do not agree, they will be found to be approximately parallel to each other, when plotted with a logarithmic frequency scale, and one can be expressed as a percentage of the other. Thus, if twice as many occurrences are reported as computed, it is safe to conclude that the probability of rainfall during floodtime is twice the normal. Because of the larger number of hourly amounts recorded, the study of hourly records is easier than the study of daily records. It is not essential that the rainfall and river stages be observed at the same place. Since the river stage is used only to identify those periods in which floods are likely as compared with the average, in the author's example, recording rainfall records at Scranton and Harrisburg could be utilized with stage records at the locality under consideration—Williamsport.

Data studied for Richmond, Va., on the James River will illustrate the point in question. Rainfall during floodtime at Richmond is rare. Almost 2 days elapse between the rainfall that produces the James River floods and the arrival of the peak at Richmond. By that time, local streams have fallen to low levels, and they rise again only if additional rain falls. By the criterion of the writer, in a preceding paragraph, floodtime rainfall should be independent and normal.

A study of the hourly and daily rainfall records of the Richmond Weather Bureau for the period 1905–1939 showed that rainfall during floodtime was no more, and no less, probable than at any other period. In 34 years the James River is normally above a stage of 8.0 ft for 4,080 hrs, 170 days, or 0.46 year. A stage of 8.0 ft was reported during each of 193 days in the period 1905–1939. Normally, rainfall of 0.01 in. or more is reported for 590 hr per yr, or 275 times in 170 days.

TABLE 3.—NORMAL RAINFALL IN INCHES, RICHMOND, VA.

Maximum probable rainfall	LENGTH OF PERIOD, IN DAYS (NOT NECESSARILY CONSECUTIVE)							
	1	2	5	10	20	50	100	200
Hourly...	0.03	0.07	0.14	0.23	0.35	0.56	0.76	0.98
Daily....	0	Trace	0.10	0.38	0.72	1.15	1.55	2.00

Table 3 shows the normal rainfall experience of Richmond. The quantities listed define the hourly and daily rainfall frequency curves from 1 to 200 days. (Note: The fact that hourly rainfall is greater than daily rainfall for short periods of time is correct, and merely means that, although rainfall of 0.01 in. or more occurs in only one of every 3 or 4 days, it usually rains for several hours when it does rain.)

The records of hourly and daily precipitation were compiled for all days, 1905–1939, inclusive, upon which a stage of 8.0 ft was reported, a total of 193 days. The precipitation for the entire day was included, regardless of whether the river remained above 8.0 ft. This inclusion is partly offset by the omission of records of days when the river has exceeded the stage for a few hours without having been reported.

Table 4(*a*) compares the normal experience of any 170 days at Richmond, selected at random, with the record of all days, 1905–1939, upon which the James River was reported above 8.0 ft. Table 4(*b*) shows a similar comparison for the experience above a stage of 20.0 ft, which is an average of 11 days in 34 years.

Tables 4(*a*) and 4(*b*) show essential agreement between the floodtime experience and that of a normal period of equal length. If the number of floodtime occurrences were 2.0 or 3.0 times the number of normal occurrences, the conclusion would be that floodtime rainfall was 2.0 or 3.0 times as probable as normal. In this case, there is no essential deviation, and the writer draws the conclusion that the probability is the same, and that the estimate of rainfall at higher stages on a similar basis is warranted.

In this connection, it is well to note that it is not necessary to have a knowledge of the true duration of floods above given stages; but it is adequate to use a flood-stage frequency curve with any assumed number of days' duration per rise. If the duration is assumed too long, the probability ratio will be correspondingly smaller. Likewise, a seasonal or monthly rainfall frequency curve could be used, instead of an annual curve as used by the writer, with a corresponding compensative change in the indicated relative probability of rainfall during floodtime and in the normal period for which a rainfall curve is available.

TABLE 4.—COMPARISON OF FLOODTIME AND NORMAL RAINFALL, RICHMOND, VA.; NO. OF OCCURRENCES

[a] During any part of a day on which a stage of 8.0 ft or higher was reported.

The writer believes that the theory of this method of analysis can be extended easily to runoff instead of rainfall. A pumping plant to be used above the 5-yr river stage, where average duration of floods is 2 days, is exposed to conditions under which it must operate for only 20 days in 50 years. One year of normal or near normal runoff would contain 18 such occurrences. Observations of runoff certainly should be made before any expensive final drainage plan is adopted.

W. W. HORNER,[15] **M. AM. SOC. C. E.**—Mr. Williams' paper deals with a class of engineering problems which appears to be occurring more and more frequently in engineering practice, and about which relatively little has been published. The title is somewhat too narrow, since the principles involved seem to apply clearly to the drainage of any relatively narrow levee-protected area where there is considerable lateral inflow from a tributary stream. For example, the writer has encountered exactly the same conditions in connection with the "industrial property" area along the Trinity River at Dallas, Tex. At this point the lateral inflow was almost entirely from storm-sewered urban areas. He also has found such conditions in his work for the East Side Levee and Sanitary District at East St. Louis, Ill., where the lateral inflow is from small streams of 1 to 20 sq miles flowing out of the higher-level Illinois bluff drainage areas. Possibly by a little stretch of the imagination, these bluff lands might be considered as mountains. In the first instance, the only possible solution was through the use of pressure conduits; and in the second, cutoff channels, detention storage, and pumping are involved.

---

[15] Cons. Engr. (Horner & Shifrin), St. Louis, Mo.

The procedure suggested by Mr. Williams is interesting, and in part new. It appears to justify some comments and a number of questions which the writer hopes that the author may be able to answer in his closing discussion. The two conditions referred to as (*a*) and (*b*) under "Local Drainage Requirements" are fundamental to all such problems. In the experience of the writer, item (*b*) is always the critical one and must be considered first, and item (*a*) should be taken up after the primary solution of item (*b*) has been determined.

Under the head of "Local Hydrology" Mr. Williams discusses the requirement for the consideration of complete hydrographs. This usually has not been undertaken in local problems of this kind, but it is fundamental to any reasonable solution. The one exception to this requirement is that of pressure conduits draining completely sewered urban areas where no storage is provided and the conduit capacity must be equivalent to the peak rate of flow from the storm sewers. For this situation, it is necessary to study the coincident probability of discharges of various frequencies with concordant stages in the main river.

In the case of the Dallas project (1931), a preliminary report had indicated pressure conduits of a capacity to carry the peak rate from the determined rainfall frequency of the urban storm system, in this instance a 5-yr frequency; but the preliminary design of the pressure conduits provided this capacity against the maximum recorded river stage in the Trinity River. This situation was quite critical to the economics of design, as the lower-lying portions of the areas served by the storm sewers were but little above the maximum recorded flood stage.

TABLE 5.—RESULTS OF LEVEES AND FLOODWAY CLEARANCE ON STAGE DURATIONS, TRINITY RIVER AT DALLAS, TEX.

Description	FLOOD FLOW (CU FT PER SEC):			
	75,000	63,000	49,000	23,000
Record Data (27 Years):				
Stage (ft)	42[a]	41	39	35
Days of above stage in 27 years	6	10	38	68
Rate of same excess with reservoirs	69,000	32,000	15,000	12,500
Stage, with cleared floodway between levees	39.5	35	33	30 ±

[a] Second high flood in 27 years; highest stage 52.6 ft.

This case was complicated by the then recent completion of reservoirs above Dallas, and by the changed régime involved in the construction of the levees and cleared floodway, and required a complex analysis of the effect of these structures on stage durations. The result of these studies is summarized in Table 5.

The required hydraulic grade to serve critical improvements in the vicinity of the head of the pressure conduit was at stage 54. The design stage at the outlet was fixed at 35, giving a drop of 19 ft in the 4,700 ft of pressure conduit.

For this situation, an additional check also was made on the actual occurrence of rainfall equal to or exceeding the 1-yr frequency, with concurrent river stages. It was found that, although many of the precipitation periods were related to the same storm which produced the river rises, these precipitation periods never occurred at the passing of the peak of the flood, and were generally related to flood stages well down on the rising side of the hydrograph. It was found that, within the duration of stages in excess of 41 (or 35 with improvements), precipitation had occurred on only 1 day and in an amount of only 0.75 in.

Mr. Williams' experiences with basic data deficiencies closely parallel those of the writer, except that the writer generally has found more adequate recording rain-gage information than seemed to be available in this instance. The installation of stream gaging stations on small areas, such as that in Mr. Williams' project, seems to the writer to be a fundamental requirement for this class of work, the value of which has not been fully appreciated heretofore. Hydrologists are too prone to think that stream-flow records are of no value until a record of a number of years is available. Actually, a good record of two or three major rises of the hydrograph for a small watershed makes unnecessary reams of calculations in the field of synthetic hydrograph preparation, most of which do not lead to very convincing results.

The author's division of both rainfall and flood stages into two major seasons would seem to be adequate for the Susquehanna River. The writer used a similar division in the Dallas studies, determining rainfall depth-frequency relations for each of two 6-month periods; but because of climatic differences, the periods were not the same as those used by Mr. Williams. A study of rainfall frequency records for the winter seasons and the use of the results as indexes appear to be valid procedures for the project described. It is to be noted that the author does not propose a similar procedure for the summer season, and the writer agrees that the indexes for that season would not be sufficiently significant.

The use of point rainfall data for the complete drainage basin seems satisfactory for the winter season, but the writer would not utilize it for summer storms where the area is appreciably in excess of 1 sq mile.

Under the head of "Local Hydrology: Design Storm for Flood Season," the author struggles with a methodology that has been a cause of concern to all hydrologists. In the writer's experience, there is no fully satisfactory answer to this requirement. The best and probably most valid answer involves not the choice of some severe storm, but the actual analysis of runoff for a large number of "severe" storms throughout the period of record, and the subjection of the results of a flood-frequency analysis. Something on this order was utilized in the writer's recent study of flood flow on the Trinity River for the U. S. Department of Agriculture. It involves a great amount of work, however—an amount that would be in excess of what normally would be undertaken for projects such as those described by the author, which involve a considerable number of small streams. The second method suggested, and the one which the author utilized in setting up a synthetic storm pattern from rainfalls of equal frequency, would seem to be definitely and probably considerably on the conservative side. The writer would hesitate to adopt it without further tests of the results. It unquestionably provides synthetic storm patterns of a much rarer and infrequent type than the chosen design frequency. A third method that sometimes has been utilized involves the setting up of a pattern for the design frequency precipitation in accordance with average occurrence. This involves a considerable analysis to determine average storm patterns, but extensive work in this field already has been done. The method was utilized by the Department of Agriculture in the Little Tallahatchie flood-control studies in Mississippi, and there are also available independent studies reported by D. I. Blumenstock.[16] The St. Louis regional rainfall records have been subjected to such studies under the supervision of the writer. Important conclusions which may be drawn from these studies are that:

(1) Such a design storm will never contain short-period intensities as great as the short-period intensities of equal frequency; and

(2) High rates will not occur at the midpoint in the storms, but more nearly at the first one-third point.

The effect of these differences is to give a somewhat flatter and somewhat more advanced histogram of rainfall than those shown by the author.

It is interesting that the author does not consider infiltration rates for the winter storms, possibly due to the fact that so little data have as yet been published for these conditions. The writer is inclined, however, to question the propriety of using the runoff as 100% of the precipitation, plus snow melt, in the design storm. It would seem that, except under very rare conditions, some infiltration and interception losses must be inevitable. The use of such a value in the maximum storm might be justified if the maximum storm were to occur in winter. The application of an infiltration "rate" of 0.3 in. per hr for summer storms, presumably of the short thunderstorm type, would seem to the writer to be overconservative. However, he is of the opinion that proper rate cannot be determined from stream flows on larger areas unless larger areas can be found that have approximately the same coverage of soil and vegetation. The only reasonable approach to the determination of a proper infiltration rate would be on the basis of studies of the identical soil and cover involved in the particular drainage basin. Otherwise, considerable error in either direction may be involved.

The writer is interested in the approach to the development of a synthetic unit hydrograph. In the Trinity River investigation, the writer, in collaboration with Waldo E. Smith, M. Am. Soc. C. E., analyzed a large number of hydrographs at the Rockwall gaging station (821 sq miles). For this station relations were developed as follows:

$$\frac{Q_p}{Q} = 0.025 + 0.07\,(Q - 0.7) \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

for values of Q, or mass surface runoff in excess of 0.7 in., and for Q_p, the peak-hour rate in inches per hour; also, from the recession curves,

---

[16] *Technical Bulletin No. 698*, U. S. Dept. of Agriculture, Washington, D. C.

$$q = K_s S \qquad (6)$$

in which q is in cubic feet per square mile and S is hour-second-feet per square mile. For Rockwall, the value of K_s was 0.046.

A study of smaller basins in the same physiographic province indicated that their relationship could be made a function of the basin area in square miles, as follows:

$$K_s = \frac{7.4}{A^{0.25}} \qquad (7)$$

for watersheds in excess of 20 sq miles. For 1 in. of runoff,

$$Q_p = \frac{1.11}{A^{0.6}} \qquad (8)$$

The base of the hydrograph in hours is

$$B = 2.5\,A^{0.6} \qquad (9)$$

and the lag time in hours from center of mass of excess rainfall to center of mass of the hydrograph is

$$L = 0.88\,A^{0.6} \qquad (10)$$

From these relationships it was possible to construct distribution graphs for basins of various areas. To these graphs excess rainfall was applied in time increments varying from 1 hr for basins of 23 sq miles or less to 6 hr for basins in excess of 200 sq miles.

These last four relationships (Eqs. 7 to 10) were most useful and were extremely helpful in working out the hydrograph form.

The use of the "time of concentration" as discussed by the author has not been found to be very satisfactory for natural drainage basins of this type, and the writer would prefer not to use a methodology that involved the so-called rational formula. He would like to call attention to the fact that the "C" in the rational formula involves both losses and delay factors. In the latter category it includes the effect of channel storage. If by some means a proper value of "C" has been determined, then it would seem that something like flood routing already has been done, and the hydrograph would include channel-storage effects above whatever point it was applied. The writer is in agreement with the statement made immediately below Eq. 4 of the paper, but would go further and state that, in most instances, such an assumption is not only conservative but excessively conservative. In general, the writer is of the opinion that much better synthetic hydrographs can be developed from a study of even two or three actual hydrographs than through any approach involving time of concentration and equal time contours. In this connection he would call attention again to the importance of doing what was done under the described projects—namely, the installation of stream gaging stations at the point where the lateral streams enter the flood plain.

WALTER T. WILSON,[17] ASSOC. M. AM. SOC. C. E.—The writer likes Mr. Williams' analytical approach, that is, studying floods by examining their causes. The logic and merit of studying floods by relating stream flow to the antecedent and causative rainfall cannot be denied. Without wishing to detract from Mr. Williams' excellent paper, the writer, feels that the study of successive causes and effects leading to floods should be carried at least one step nearer the first cause. The Hydrometeorological Section of the Weather Bureau has been studying the causes of major storms.

The expression "maximum probable" flood seems unsatisfactory because the term "maximum" implies an upper limit, whereas the term "probable" involves a wide range of meaning and begs a specific definition. A flood or a storm must have a finite physical upper limit. The writer, with an increasing number of hydrologists and meteorologists, is perfectly willing to "stick his neck out," and study this thing of which all hydrologists are thinking—the "maximum possible" storm or flood.

Storm magnitude is determined and limited by the nature and magnitude of its causes. These include the available quantity of moisture in the air, the rate at which moisture laden air flows into the flood area, and the rate at which the moisture can be condensed and precipitated. These factors have finite limits, which involve an admittedly difficult but not hopelessly impossible study.

By way of adverse criticism, the writer feels that the subject of snow is passed by with an inadequacy both in its treatment and melting rate. Mr. Williams' estimated design rate of an inch of snow melt per day has an obscure basis and seems too low. This is in contrast not only to reasonable degree-day factors but also in contrast to actual records. Reference is made to the 1936 flood in New England. The total runoff for the second storm period (March 16 to 19) from the basin of the East Branch of the Pemigewasset River, above Lincoln, N. H. (104 sq miles), has been estimated at 12 in. to 15 in. The nature of the topography and lack of good precipitation data require estimation of the precipitation during this period, which by preparation of isohyetal maps and careful consideration of meteorological factors indicates a value of 4-in. to 5-in. average depth. The difference between the 12 in. to 15 in. of runoff and the 4 in. to 5 in. of rain probably includes some ground-water contribution, but leaves about 8 in. of snow. The writer believes that at least 4 in. of snow melted and ran off in less than one day. By assuming a reasonable velocity of concentration and a reasonable ratio of stream length to basin area, Eq. 4 "boils down" to a Myer's rating of about 30% to 50%.

Under the heading "Local Drainage Requirements," the author states that flood protection from small tributaries is rarely justified. The writer realizes the danger of separating one sentence from the remainder of the text, and may not understand the meaning in this case. However, Mr. Williams has exposed himself to criticism by proponents of upstream engineering and flood control in source regions.

[17] Asst. Hydrologic Engr., Weather Bureau, Washington, D. C

W. B. Langbein,[18] **Assoc. M. Am. Soc. C. E.**—Any treatment of the flood problem even though directed to one specific design is likely to involve the application of a large range of hydrologic principles. The designer of drainage structures or leveed areas finds it necessary not only to familiarize himself with, but also to evaluate, rainfall and snow-melt characteristics, the absorptive qualities of the ground and the laws of open-channel flow, besides the hydraulic and mechanical properties of the drainage structures themselves. There is special need, therefore, for methods of solving the many hydrologic questions that arise in the design of hydraulic structures and are common to most flood and even drought problems. Methods of treatment in one of them merit consideration in another, and Mr. Williams' paper, although perhaps limited in title, contributes much to this end.

The writer was most interested in Mr. Williams' construction of flood discharge hydrographs from known or assumed amounts of effective rainfall and snow melt. This feature of the rainfall-runoff relation has been a favorite subject for some years; and with increasing experience, fairly satisfactory results have been attained, mainly through the unit hydrograph, a hydrologic tool which reaches its tenth anniversary this year (1942). However, there is noted in Mr. Williams' treatment a co-mingling of the so-called rational method of earlier origin with a synthetic unit-graph method. At the possible risk of confusing the subject, the writer offers the following method for solving Mr. Williams' problem, which breaks away entirely from the so-called rational procedure, substitutes some of the newer unit-graph technique and flood-routing principles, and yet is believed to be as direct and simple as the method used by Mr. Williams.

Fig. 7 shows standard dimensionless unit hydrographs based on a dimensionless S-hydrograph previously derived by the writer.[19] The scale is expressed in terms of the lag between center of mass of effective rainfall and flood runoff, a constant or near constant for any drainage basin. The lag has three other corollary meanings: (1) It is equal to the quotient between an increment in storage in the basin and the corresponding increment in discharge; thus it represents the storage element, and is equivalent to the flood-routing coefficient K;[20] (2) it is equal to a weighted mean time of wave travel from the several component parts of the basin; and (3) it is equal to the storage coefficient as derived from recession limbs of flood hydrographs. It is computed by either comparing times of center of mass of effective rainfall and center of mass of direct runoff, or by analysis of the recession curve.[21] The lag thus defined and computed is descriptive of the storage and concentration characteristics of a basin and may be correlated with basin topographic characteristics in ways dependent on local conditions. Generalizations cannot be given; in some regions, good correlations can be obtained simply with length of a basin; in others, the slope or altitude needs to be introduced. F. F. Snyder,[22] Jun. Am. Soc. C. E., has published data applicable to Pennsylvania, and G. T. McCarthy,[20] Assoc. M. Am. Soc. C. E., has derived a method applicable to the Connecticut River Basin. With such correlations a unit hydrograph for application to ungaged areas within a limited region can be approximated. The procedure then is as follows: Suppose a basin of 3 sq miles has a lag of 1.67 hr and it is desired to compute the peak discharge using rainfall of critical duration conforming to the design storms given in Fig. 2. For a 10-yr storm the amounts of the rainfall plus snow melt in specified periods of time are given in Col. 3 of Table 6. Col. 2 of this table contains the time scale expressed non-dimensionally in terms of the basin lag (100 min in this example). The peak of unit graphs of various durations of inflow (in terms of lag) is given by the envelope curve of Fig. 7. The corresponding values are entered in Col. 4, Table 6. It will be noted that for lengthening storm durations the volume of supply increases, whereas the peak of a unit hydrograph decreases. What is the critical duration of the given storm-rainfall-characteristics of this basin? The answer

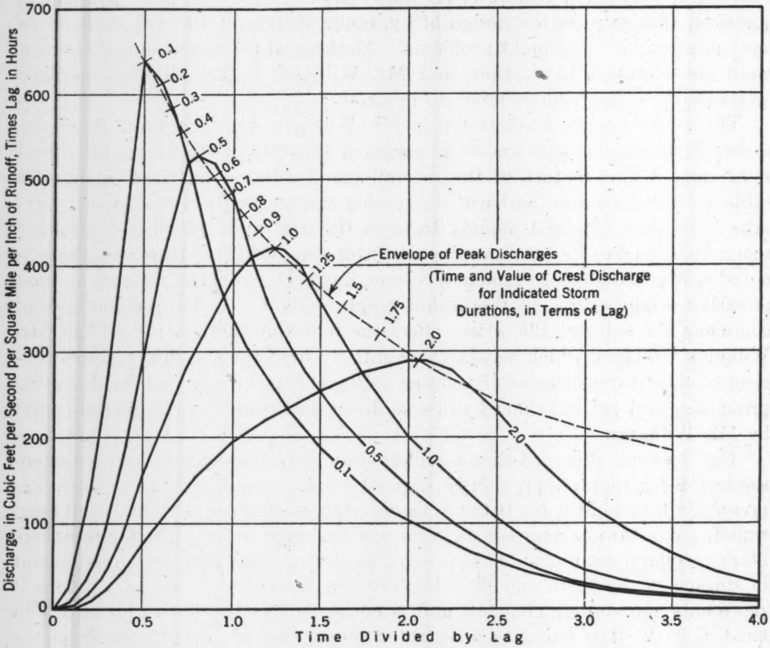

FIG. 7.—DIMENSIONLESS DIAGRAM SHOWING FAMILY OF STANDARD UNIT HYDROGRAPHS FOR SEVERAL SELECTED DURATIONS OF RUNOFF GENERATION

is found in Col. 6, which is the product of Cols. 3 and 4. A storm of 120-min duration gives the maximum peak of this basin. The formula is thus:

---

[22] "Synthetic Unit-Graphs," by F. F. Snyder, *Transactions*, Am. Geophysical Union, 19th Annual Meeting, Pt. 1, 1938, pp. 447–454.

$$Q_p = S \frac{\text{Vol}}{\text{Lag}} \qquad \text{(11}a\text{)}$$

or

$$Q = S \frac{\text{Vol}}{\text{Lag}} A \qquad \text{(11}b\text{)}$$

in which Q_p is the discharge in cubic feet per second per square mile, Q is the discharge in cubic feet per second, S is the ordinate of Fig. 7, and A is drainage area in square miles. A unit hydrograph for the critical duration can then be read from the family of graphs given in Fig. 7.

TABLE 6.—COMPUTATION OF FLOOD-PEAK DISCHARGES FOR STORM PERIODS OF SELECTED DURATIONS

TIME		Volume of supply (in.) ×	Peak of graph (Fig. 7) (csm-hr per in.)[a] ÷	Lag (hr) =	Peak discharge[a] Q_p
Minutes (1)	Lag (%) (2)	(3)	(4)	(5)	(6)
0	0	0	...	...	...
30	0.30	0.55	585	1.67	193
60	0.6	0.75	500	1.67	224
90	0.9	0.92	440	1.67	242
120	1.2	1.05	390	1.67	245 = Max.
150	1.5	1.14	350	1.67	239
180	1.8	1.22	315	1.67	230
210	2.1	1.29	280	1.67	216
240	2.4	1.35	250	1.67	202

[a] Cubic feet per second per square mile.

The writer proposes the lag time as a measure of the time-discharge characteristics of drainage basins in lieu of the so-called time of concentration. The time of concentration is a concept that has not been, and seemingly cannot be, defined accurately. For example, the usual definition is the "time required for rainfall excess to flow from the most remote part of the basin to the gaging station." Mr. Williams adapts another to his problem—the time required for runoff to equal the rate of rainfall excess. Still another is the time between beginning of the flood rise and its peak. It has never been demonstrated that these are equivalent. Incidentally, C. E. Ramser, M. Am. Soc. C. E., used the latter meaning in determining time of concentration which Mr. Kirpich used in his article, to which Mr. Williams referred.[7] In discussing Mr. Kirpich's article,[23] the writer stated that the correlation presented was equivalent to a velocity of 4 ft per sec and the inclusion of the slope factor was not well supported by the available evidence. The lag time, however, can be computed in more than one way, each of which is theoretically equivalent subject only to errors or limitations of data.

Eq. 11*b* is similar in form to Eq. 4 if the latter is multiplied by the volume of runoff, except that lag is used to evaluate the storage effect and no assumption need be made as to the critical length of the storm. It is proposed for use instead of the "rational" formula $Q = C\,i\,A$. Insufficient data are given by Mr. Williams to compare the results obtained by the two methods, except to the following extent:

---

[23] *Civil Engineering*, August, 1940, p. 533.

Fox Hollow Run, according to Fig. 4, has a lag (center of mass of supply to center of mass of hydrograph) of 20 min.

In dimensionless terms the peaks of the hydrographs shown are as follows:

(1) "Ten-minute rainfall period" = 0.50 lag; $\dfrac{1{,}300\ \dfrac{\text{ft}^3}{\text{sec-in.}}}{\dfrac{548}{640}\ \text{miles}^2} \times 0.33\ \text{hr}\ (= \text{lag})$ = 500 (no units). The envelope curve in Fig. 7 for inflow period of 0.5 lag gives 530.

(2) "Thirty-three-minute rainfall period" = 1.67 lag; $\dfrac{1{,}000\ \dfrac{\text{ft}^3}{\text{sec-in.}}}{\dfrac{548}{640}\ \text{miles}^2} \times 0.33$ hr (= lag) = 388. The envelope curve in Fig. 7 for inflow period of 1.67 lag gives 330.

GORDON R. WILLIAMS,[24] ASSOC. M. AM. SOC. C. E.—The volume of discussion pertaining to this paper was gratifying to the writer, particularly since the subject was not one to arouse interest during wartime. Many interesting angles were stressed, and considerable space could be devoted to developing further the points in question. There was general agreement that the title of the paper was too restricted and that the principles presented have wide application to drainage problems, both urban and rural, in many parts of the United States.

In discussing the methods of disposing of local drainage, Mr. Bernard proposed an additional method, or rather a combination of methods, in which a secondary levee and pumping station would be provided upstream from the main river levee and pumping station. Such a method might be worthy of consideration under special conditions, but the use of two sets of pumping installations and gates rarely would be justified from an economic standpoint.

The importance of having adequate levee heights under method (1) was demonstrated by Mr. Sherman with an example. The writer has utilized the following method for developing adequate height for tributary levees:

(*a*) From known records of discharges, develop a relation between coincident flood discharges on the main river and on the tributary;

(*b*) Compute flow lines up the tributary, using a range of coincident discharges; and

(*c*) Draw an envelop of the flow lines.

The envelop curve plus a normal freeboard for wave action will constitute the levee profile. The height of the downstream end will be governed by the magnitude of the design discharge in the main river, but the height of the upstream end usually will be governed by the magnitude of the design discharge in the tributary. In this connection, Mr. Sherman took exception to the statement that "A corresponding degree of protection is not required against flows from tributaries that pass through leveed areas." This statement was intended to apply particularly to the capacity of structures such as pressure conduits and pumping stations. The writer agrees with Mr. Sherman that in the application of method (1) the statement should not be taken too literally and that adequate upstream height is well worth the relatively small additional cost. On other types of drainage structures, it is obviously not sound engineering practice to provide discharge capacity for a flood having a probable frequency of occurrence of once in a hundred years or less.

---

[24] Hydr. Engr., U. S. Engr. Dept., Wilkes-Barre, Pa.

Mr. Sherman commented on the high pumping capacities in inches per day, shown in Fig. 5, as compared with pumping capacities found necessary for leveed areas on the Illinois and upper Mississippi rivers. The latter areas are flat, provide much more storage per square mile of tributary area, and have a resulting delayed runoff. The pumping stations along the Susquehanna River must dispose of a hydrograph resulting from quick runoff from mountain slopes. Records of flood runoff coincident with high stages in the Susquehanna River already have been obtained on one area of 18 sq miles and indicate that a pumping capacity of 0.8 in. per day in connection with more than 2.0 in. of flood-plain storage will be required to meet conditions which have already been experienced and which were not unusual. Such a capacity is in close agreement with the mean curve in Fig. 5.

Several of the discussers questioned the assumed rate of snow melt of 1 in. in 24 hr in connection with the design storm. Messrs. Bernard and Wilson considered the rate too low, whereas Mr. Horner considered that the use of 100% runoff plus snow melt is too conservative. The writer admits that there were few data upon which to base the assumption, but is interested to note the wide divergence of opinion among recognized specialists in hydrology. The selected rate of snow melt was intended to have the same probable frequency of occurrence as the design storm rainfalls—namely, 5 to 15 years. Actually, the rate of snow melt, which is only 0.04 in. per hr, has little effect on the peaks of the hydrographs and is merely inserted for its influence on the 1-day and 2-day storage requirements.

Mr. Wilson took exception to the statement that "Flood protection from small tributaries is very rarely justified," and stated that the writer "has exposed himself to criticism by proponents of upstream engineering and flood control in source regions." In making the statement the writer has reference to the economic justification for the erection of expensive structures, such as large storage dams, when the benefits are to accrue only to the tributaries themselves. The burden of proof of the efficacy as well as the justification of other methods, such as terraces, check dams, and crop control, is squarely up to the proponents of such methods. The determination of the annual charges for such work will not be difficult, but the computation of the reduction in flood stages at points downstream for floods of different magnitudes and frequencies will test the ingenuity of agricultural engineers and agronomists.

The use of the rational formula (Eq. 2) to determine the peak of the time of concentration unit hydrograph received considerable comment. Mr. Langbein and Mr. Sherman were of the opinion that the writer was attempting to establish a new definition for time of concentration, but that was not the case. The confusion seems to result from the fact that the writer was concerned only with rainfall that would run off—that is, rainfall excess. In accordance with the rational theory, if a uniform rainfall falls on saturated soil and continues to fall until all parts of the area are contributing, the theoretical rate of runoff will equal the assumed uniform rainfall rate and will continue at that rate as long as the rainfall continues. Mr. Horner pointed out that the *C* in the rational formula, as generally used, involves both losses and delay factors. By using a time of concentration derived from actual stream-flow records, the writer has introduced, in part at least, some of the delay factors. Some of the conservatism derived from the use of the rational theory is nullified in the application of the final flood hydrographs, which are greatly modified by routing through existing storage and constrictions. It is agreed that the method of deriving the unit hydrograph is conservative, and should not be resorted to if actual records are available.

Messrs. Horner and Langbein presented methods of deriving synthetic unit hydrographs by correlation of lag time with the characteristics of recorded hydrographs. The writer believes that the principles involved are perhaps superior to those presented in his paper, but are difficult to apply for the following reasons:

(*a*) Records of complete hydrographs from areas of less than 10 sq miles are difficult, if not impossible, to obtain for a wide variety of drainage area characteristics; and

(*b*) The extrapolation and application to very small areas of relations obtained from hydrographs for relatively large areas will lead to erroneous results and to serious under-design.

Mr. Clark considered, in detail, studies for determining rainfalls expected to occur coincident with different river stages. The writer agrees that this is the ideal solution for drainage areas tributary to large rivers or at any locality where there are sufficient records. The results of a study of this kind have been presented by Frank A. Marston,[25] M. Am. Soc. C. E. Rainfalls coincident with different river stages were considered in Mr. Horner's discussion, where he outlined the problem of the design of a pressure culvert at Dallas, Tex.

The expression "maximum probable" flood is questioned by Mr. Wilson, and he prefers the term "maximum possible" flood. The writer agrees that his expression involves two words which are somewhat contradictory, but what he attempted to determine was an extraordinary flood which by nature could not be defined within close limits. If the "maximum possible" flood could be determined, it would have no application to the structures under consideration, and would have little application to engineering design except in the determination of reserve spillway capacity for very large dams. The advisability of using even the "maximum probable" flood in determining the capacity of relief openings is questionable, except where great damage will result from backwater. As stated in the description of method (2), it will be found in many cases to be good engineering and sound economic practice to plan to blow a hole in earth levees in the case of a very rare occurrence rather than spend large sums on oversized gates and culverts.

TIMBER FRICTION PILE FOUNDATIONS

By Frank M. Masters,[1] M. Am. Soc. C. E.

With Discussion by Messrs. E. H. Connor, Glenn B. Woodruff, Jacob Feld, G. G. Greulich, G. S. Paxson, Raymond D. Mindlin, John W. Solomon, A. E. Cummings, and Frank M. Masters.

Synopsis

The theory of timber friction pile behavior presented in this paper was developed in connection with pile tests on the Morganza Floodway in Louisiana. It may afford a means of determining, with reasonable accuracy, the safe loads to impose on groups of piles in any arrangement, and of any length, from data secured by the loading to failure of one or more individual friction piles at the site.

Introduction

Many large areas of land in the United States on which structures imposing heavy foundation loads are constructed are formed of silty and clayey materials, being delta deposits of the larger streams. Sandy deposits or other such firm materials suitable for the support of heavy concentrated foundation loads are frequently found at such great depths below the surface of these deposits that it is not economically possible to construct foundations that bear directly on the firm materials, or that are supported on point bearing piles driven into these firm materials. Moreover, timber piles, which are relatively inexpensive and of remarkable durability when embedded entirely below the ground water, are becoming increasingly scarce in the longer lengths required to reach such firm bearing strata. Consequently, many existing structures are supported on piles embedded in the overlying silt and clay materials. It is becoming more and more important, therefore, to find some reasonably accurate method of determining the safe carrying capacity of single piles and groups of piles that do not reach point bearing in a firm stratum, but depend instead for their support entirely upon the adhesion of the surrounding clay or silt to the embedded pile surfaces.

Such piles, popularly called "friction" piles, are the subject of analysis in this paper. The adhesion that supports them transmits their load to the soil

---

[1] Cons. Engr. (Modjeski & Masters), Harrisburg, Pa.

by vertical shearing stresses, which are greatest in the soil at the periphery of the single pile or of the pile group.

The tip of a "friction" pile delivers practically no load in bearing, so that the load-carrying capacity of a single pile is dependent upon the length of the pile, the diameter and taper of the pile, and the shearing strength of the soil. The last may increase somewhat from the surface downward due to the additional internal friction generated in the soil on account of horizontal earth pressures from the weight of the overlying materials. However, due to the fact that the butt diameter of timber piles is larger than the tip diameter, the load delivered to the soil per unit of length of a timber pile will usually be greatest at the butt and smallest at the tip.

Load tests have shown that pile-driving formulas, in which the weight of the ram and the blows per foot of penetration are used to determine the carrying capacity of the pile, do not apply to friction piles, probably because the characteristics of clay or silt during driving are different from what they are when the pile is at rest in the clay or silt. Static load tests which simply measure the load that creates a predetermined amount of settlement within a fixed amount of time, also do not properly measure the ultimate carrying capacity of friction piles, which is measured rather by the shearing value of the soils in which the piles are embedded than by the compressibility of the underlying materials.

It has long been known that an average individual pile in a group arrangement of friction piles does not have the same carrying capacity as an isolated single pile and that the arrangement and spacing, center to center, of the piles in a group affect the load capacity of the piles. Because of the lack of tests to failure of group arrangements of friction piles, compared with individual friction piles driven in the same character of soil, there has been little or no comparable information available concerning the supporting capacity of single piles and piles in group arrangements with varying spacing, from which a theory might be developed for the economic design of friction pile footings.

THE MORGANZA PILE TESTS

As a part of the Mississippi River flood-control program, the U. S. Engineer Corps is required to construct railway and highway structures across the Morganza Floodway in Louisiana. In order to determine the most economical design of these structures, which are being erected by the railway lines, the Engineer Corps arranged with the railway companies to make tests of various types of piles on which to support the proposed trestles. The results of these tests have been made available by the Corps of Engineers for use in this paper. The locations of these tests, along the lines of the proposed railway structures, with relation to borings and subsurface investigations, are shown in Fig. 1. It excludes those tests carried to point bearing and shows only the tests of timber and concrete friction piles that were loaded to failure. The soil above the "sand line" in Fig. 1 is of approximately uniform quality along the Floodway, consisting of successive strata of loam, silt and clay, and mixtures of those materials. At the Port Allen (La.) Branch Crossing (not shown in Fig. 1), pile C22, Station 2348 + 70, has 77.5 ft of penetration, with its tip just reaching the sand line. The driving records show that until a pile had reached the sand stratum, where it came up suddenly, the blows per foot increased only gradually

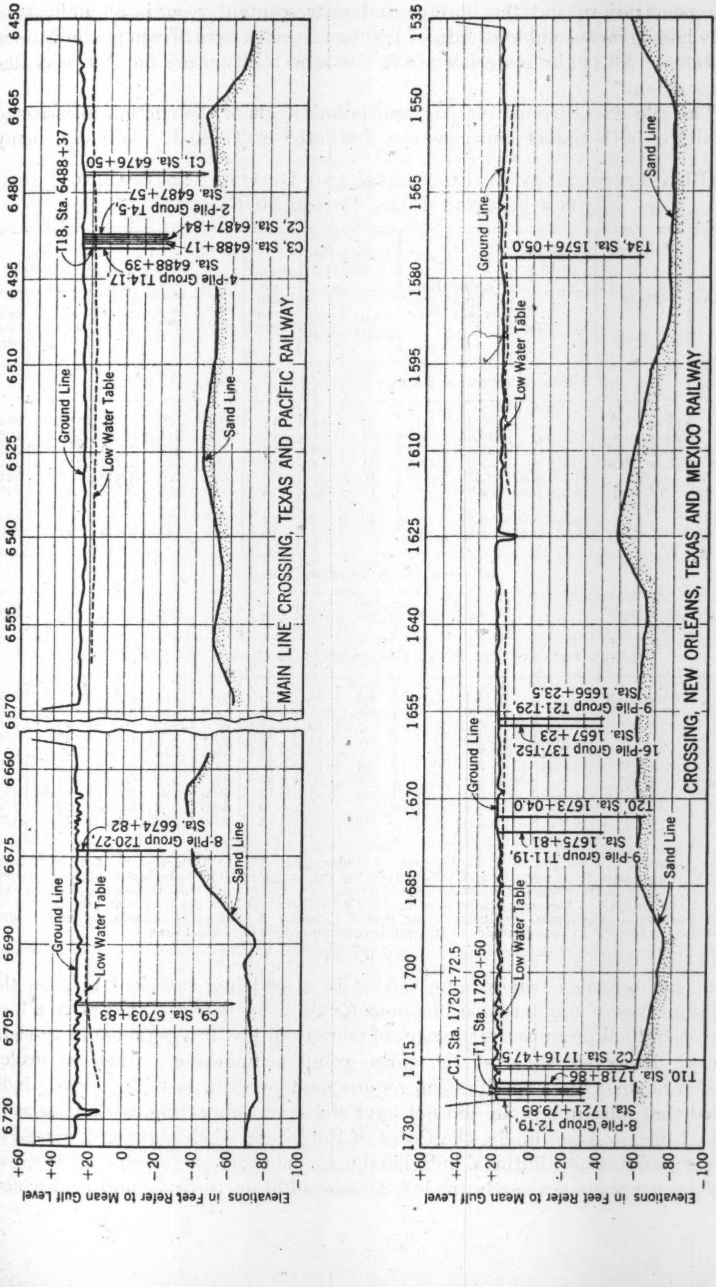

FIG. 1.—PROFILES OF RAILWAY CROSSINGS OF THE MORGANZA FLOODWAY SHOWING LOCATIONS OF FRICTION PILES TESTED TO FAILURE

with penetration, and the borings and water-content records all indicate a fairly homogeneous material into which the test piles were driven at the various locations. All of the materials above the sand stratum are of silty, clay-like composition.

The pile sizes, driving records, and failure loads of the friction piles tested to failure, both timber and concrete, are given in Table 1. Actually, many tests, not recorded herein, were carried to a load just sufficient to meet the requirements of standard specifications for timber pile tests—that is, to a load that would not produce a settlement of more than ¼ in. in a period of forty-eight hours. However, some of the early group arrangements when so loaded settled beyond these specification requirements, and in so failing clearly indicated that piles in a group did not have the same supporting capacity as individual piles. Accordingly, the Corps of Engineers, when requested, agreed to load to failure one additional individual pile, and two 9-pile groups, all of which had been previously partly loaded, and in addition to drive and load a new

[a] Data for groups T37–T52 and retest group T11–T19, plotted in Figs. 2 and 3, are not included in Table 3. [b] After 243 days, no appreciable increase in settlement was observed. [c] The group was leaning, settling 0.082 ft toward a corner having the piles with the smallest diameters. [d] Load was now removed because of the steepness of the settlement curve. [e] Group failed by tipping and breaking piles. [f] After unloading, the group had an average permanent settlement of 0.042 ft.

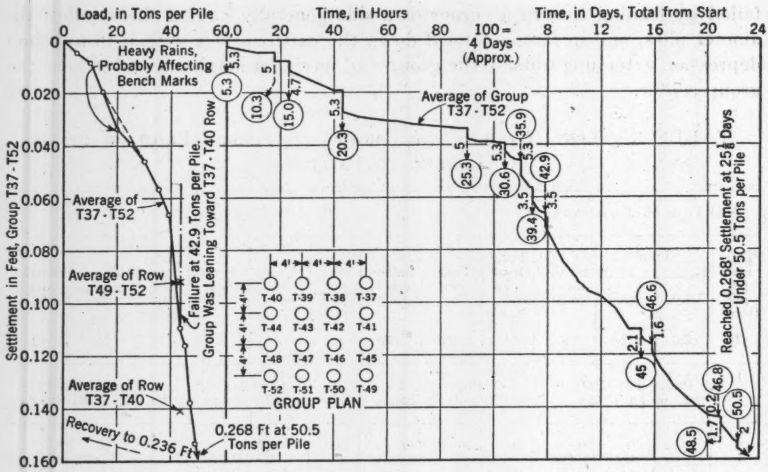

FIG. 3.—SIXTEEN-PILE GROUP T37–T52; 60-FT PILES; N.O.T. & M. CROSSING

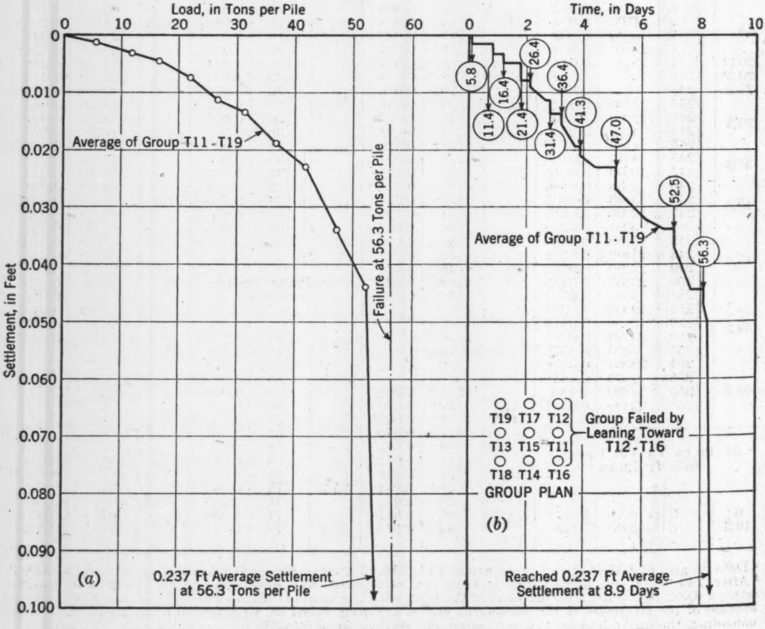

FIG. 4.—RETEST—NINE-PILE GROUP T11–T19; 60-FT PILES; N.O.T. & M. CROSSING

As illustrated in Fig. 2, the test loads were applied in the form of long, narrow, concrete blocks completely spanning the group and laid crosswise in successive layers. They were applied in increments until failure had been reached as indicated by "plunging" or by a continuation of settlement with time. These concrete blocks were supplemented in the case of the 16-pile group by additional loads in the form of water tanks. Settlements were measured accurately from bench marks in the ground surface that were far enough from the groups not to be influenced by the loads.

The results of all tests, to failure, of timber piles plotted both with relation to the load and settlement, as well as to the time and settlement, are given in Tables 2 and 3 and in Figs. 3 and 4. In these figures, the numbers in circles are the total loads per pile, in tons. The numbers on the adjoining arrows are load increments. These tests all demonstrate that larger groups fail more slowly than smaller groups and that individual piles fail by plunging. Table 4 gives the skin friction values at failure for each of the timber friction piles loaded to failure, and for each of the concrete friction piles loaded to failure.

[a] In pounds per square foot of embedded area based on the average diameter.

The parallel-sided concrete piles, when loaded to failure, did not develop the same supporting capacity per unit of embedded area as did tapered timber piles, although one would assume that the frictional resistance of the surface of a concrete pile should be at least equal to the frictional resistance of the smooth surface of a timber pile. This may be due either to the wedging action of the tapered timber pile or to some very favorable stress distribution along its sides due to the taper. The average skin friction of all tapered timber piles loaded to failure in this series of tests was 778 lb per sq ft of embedded area, whereas the average for the parallel-sided concrete piles was only 558 lb per sq ft.

NOTATION

The following notation is used in this paper:

L = length of pile as driven;

L_1 = depth from pile tip to point in ground below tip;

P = applied load; P' = point load, or load delivered by circumferential band of height dz;

q_h = unit horizontal pressure in radial direction;

q_v = unit vertical pressure;

R = diagonal distance from point load to point in soil at which pressure or shear is desired;

R_c = ratio of load delivered per linear foot of pile at top of pile to load delivered per linear foot at bottom of pile;
r = radial distance from pile center to point in ground;
s_v = unit vertical shear perpendicular to r;
s_x = unit horizontal shear parallel to x;
Z = depth from ground surface to point in ground above pile tip;
Z_1 = depth from ground surface to point in ground below pile tip.

THEORY OF FRICTION PILE BEHAVIOR

Various theories and formulas for the distribution of the load delivered by a pile to the soil were considered in this study. An attempt was made to apply some simple rule for the distribution of pile loads like the straight-line distribution at 60° to the horizontal that is common in some specifications; but this series of tests when plotted would not support any straight-line treatment, and pointed to the necessity for a more complex treatment; nor did the test results appear to check the formulas proposed by R. D. Mindlin,[2] Assoc. M. Am. Soc. C. E., which prescribe tension in the soil for loads applied beneath the ground surface. Only the classic Boussinesq formulas for the distribution of pressure through homogeneous material beneath a point load, when expanded for application to a line load, were found to check with the test results. If further tests are made, they may reveal that some simple and yet reasonably approximate

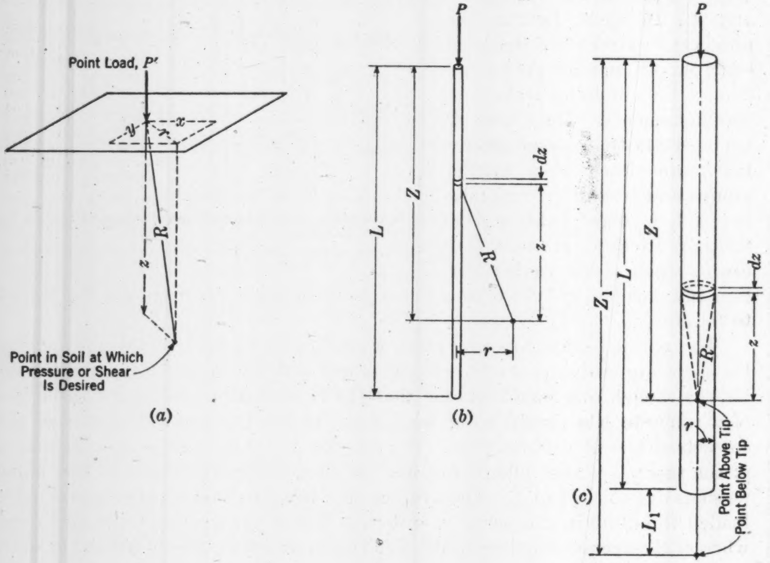

FIG. 5.

---

[2] "Force at a Point in the Interior of a Semi-Infinite Solid," by Raymond D. Mindlin, *Physics*, May, 1936.

theory may be applicable. The Boussinesq point-load formulas, which have been used frequently to determine pressures beneath buried foundations, and which were made the basis of the following analysis, are as follows (see Fig. 5(*a*)):

The unit vertical pressure (parallel to the z-axis) is

$$q_v = \frac{3\,P'\,z^3}{2\,\pi\,R^5} \qquad \text{(1a)}$$

The unit horizontal pressure, parallel to r (if Poisson's ratio for the soil is 0.5), is

$$q_h = \frac{3\,P'\,r^2\,z}{2\,\pi\,R^5} \qquad \text{(1b)}$$

The unit vertical shear, perpendicular to r, is

$$s_v = \frac{3\,P'\,r\,z^2}{2\,\pi\,R^5} \qquad \text{(1c)}$$

The unit horizontal shear, parallel to x, is

$$s_x = \frac{3\,P'\,x\,z^2}{2\,\pi\,R^5} \qquad \text{(1d)}$$

The unit horizontal shear, parallel to r, is numerically equal to that in Eq. 1*c*.

A friction pile delivers to the soil a vertical line of load through vertical shearing stresses, developed at the surface of the pile, to result in bearing pressures beneath the pile and shearing stresses around it. It was, therefore, necessary to expand Boussinesq's point-load formulas for pressures and shears by integration to apply to such a vertical line of load. These integrations follow:

Vertical Shear at Radius "r" from Pile.—If the load delivered to the soil per linear foot of pile varies from some value at the tip to R_c times that value at the butt, the load delivered by any circumferential band of height dz (see Fig. 5(*b*)) may be regarded as a point load having the value:

$$P' = \left[1 + \frac{z + L - Z}{L}\,(R_c - 1)\right]\frac{2\,P\,dz}{L\,(R_c + 1)}$$

$$= \left[\frac{(L\,R_c - Z\,R_c + Z) + z\,(R_c - 1)}{L}\right]\frac{2\,P\,dz}{L\,(R_c + 1)} \qquad \text{(2a)}$$

Based on the Boussinesq formula,

$$s_v = \frac{3\,P'\,r\,z^2}{2\,\pi\,(r^2 + z^2)^{2.5}} \qquad \text{(2b)}$$

the vertical shear at a point above the tip at depth Z is:

$$s_v = \int_0^z \frac{3\,r\,z^2}{2\,\pi\,(r^2 + Z^2)^{2.5}}\left[\frac{(L\,R_c - Z\,R_c + Z) + z\,(R_c - 1)}{L}\right]$$

$$\times \frac{2\,P\,dz}{L\,(R_c + 1)} = \frac{P\,r}{\pi\,L^2\,(R_c + 1)}\left[\frac{(L\,R_c - Z\,R_c + Z)Z^3}{r^2\,(r^2 + Z^2)^{1.5}}\right.$$

$$\left. + (R_c - 1)\left(\frac{2}{r} - \frac{Z^2}{(r^2 + Z^2)^{1.5}} - \frac{2}{(r^2 + Z^2)^{0.5}}\right)\right] \qquad \text{(2c)}$$

Vertical Pressure at Radius "r," or on Axis of Pile of Radius "r."—If the load delivered to the soil per linear foot of pile varies from some value at the tip to R_c times that value at the butt, the load delivered by any circumferential band of height dz (see Fig. 5(c)):

$$P' = \left[1 + \frac{z + L - Z}{L}(R_c - 1)\right]\frac{2\,P\,dz}{L\,(R_c + 1)}$$

$$= \left[\frac{(L\,R_c - Z\,R_c + Z) + z\,(R_c - 1)}{L}\right]\frac{2\,P\,dz}{L\,(R_c + 1)} \quad \ldots\ldots\ldots (3a)$$

Based on the Boussinesq formula,

$$q_v = \frac{3\,P'\,z^3}{2\,\pi\,(r^2 + z^2)^{2.5}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

the vertical pressure at a point above the tip at depth Z is

$$q_v = \int_0^z \frac{3}{2\,\pi} \times \frac{z^3}{(z^2 + r^2)^{2.5}} \times \frac{(L\,R_c - Z\,R_c + Z) + z\,(R_c - 1)}{L}$$

$$\times \frac{2\,P\,dz}{L\,(R_c + 1)} = \frac{3\,P}{\pi\,L^2\,(R_c + 1)}\left\{-\frac{(L\,R_c - Z\,R_c + Z)\,(3\,Z^2 + 2\,r^2)}{3\,(r^2 + Z^2)^{1.5}}\right.$$

$$+ \frac{2\,(L\,R_c - Z\,R_c + Z)}{3\,r} + (R_c - 1)\left[-\frac{Z^3}{3\,(Z^2 + r^2)^{1.5}}\right.$$

$$\left.\left. - \frac{Z}{(Z^2 + r^2)^{0.5}} + \log_e\left(\frac{Z + (Z^2 + r^2)^{0.5}}{r}\right)\right]\right\} \quad \ldots\ldots\ldots (3c)$$

The Vertical Pressure at Any Point Below the Tip at Depth Z_1.—The load delivered by any circumferential band of height dz:

$$P' = \left[1 + \frac{(z - L_1)}{L}(R_c - 1)\right]\frac{2\,P\,dz}{L\,(R_c + 1)}$$

$$= \left[\frac{(Z_1 - R_c\,L_1) + z\,(R_c - 1)}{L}\right] \times \frac{2\,P\,dz}{L\,(R_c + 1)} \quad \ldots\ldots\ldots (4a)$$

Applying the limits of Z_1 and L_1, the vertical pressure at a point below the tip is expressed by

$$q_v = \frac{3\,P}{\pi\,L^2\,(R_c + 1)}\left\{\frac{-(Z_1 - R_c\,L_1)\,(3\,Z^{2}_{1} + 2\,r^2)}{3\,(r^2 + Z^{2}_{1})^{1.5}} + (R_c - 1)\right.$$

$$\times \left[\frac{-Z^{3}_{1}}{3\,(Z^{2}_{1} + r^2)^{1.5}} - \frac{Z_1}{(Z^{2}_{1} + r^2)^{0.5}} + \log_e\left(\frac{Z_1 + (Z^{2}_{1} + r^2)^{0.5}}{r}\right)\right]$$

$$+ \frac{(Z_1 - R_c\,L_1)\,(3\,L^{2}_{1} + 2\,r^2)}{3\,(r^2 + L^{2}_{1})^{1.5}} - (R_c - 1)\left[\frac{-L^{3}_{1}}{3\,(L^{2}_{1} + r^2)^{1.5}}\right.$$

$$\left.\left. - \frac{L_1}{(L^{2}_{1} + r^2)^{0.5}} + \log_e\left(\frac{L_1 + (L^{2}_{1} + r^2)^{0.5}}{r}\right)\right]\right\} \quad \ldots\ldots\ldots (4b)$$

For pressures on the pile axis, use a value of r equal to the radius of the pile at, or immediately above, the point in the ground. Precisely the same formulas determine the vertical pressures around a pile, assuming it to be a vertical line of load, and setting r = radial distance from the pile axis.

The ratio "R_e" introduced in these integrations produces flexibility in the theory. As applied to timber piles, it takes account of the natural pile taper as well as the internal friction of the soil. When an untreated timber friction pile is withdrawn from soil after having been loaded, it is generally coated with a thin film of the material, indicating excellent adhesion between the pile and the soil, and showing that failure occurred by shearing the soil. Fig. 6.—Vertical Shears (in Pounds per Square Foot) Under Loads of 10 Tons per Pile (L = 60 Ft; Diameters at Butt and Tip, 14 In. and 8 In.; 4-Ft Spacing; and R_e = 1.5)

shearing strength of the soil were constant from butt to tip, the load delivered by shear to the soil per linear foot of pile would vary with the diameter and would be greater at the butt than at the tip. Since the shearing strength of the soil is slightly increased from butt to tip, however, as a result of a build-up of internal friction due to greater horizontal earth pressures toward the tip, this ratio of butt load to tip load per linear foot of pile will be somewhat less than the ratios of the diameters, and may be represented by the factor R_c, which appears in the pile formulas. This factor is a function of pile length, pile taper, and internal friction of the soil.

The shears existing around a single pile, a 9-pile group, and a 16-pile group, using the derived formulas for vertical shears, are presented graphically in Fig. 6. The shears are based on the assumption of $R_c = 1.5$, which value substantially checks the test results for timber piles. The computations were facilitated by the use of the curves of Fig. 7, in which the general shear formula (Eq. 2c) is plotted for various depths around a pile of unit length and under a

(b) PRESSURES UNDER 10 TONS PER PILE

FIG. 8.—VERTICAL SHEARS AND PRESSURES AROUND 60-FT PILES (Diameters at Butt and Tip, 14 In. and 8 In.; 4-Ft Spacing; and $R_s = 1.5$)

load of one unit. To find the shear around a pile of any length L, under a load P, multiply the vertical shear from these curves by the factor $\frac{P}{L^2}$. Fig. 6 shows that the vertical shear effects overlap when piles are placed near each other, and result in maximum shear stresses on the outer surfaces of the perimeter piles in a group, which are greatest at the corner piles. Hence, failure is likely to occur by the development of excessive vertical shears outside the edge or corner piles. This was indicated by the Morganza tests when a group failed by leaning toward a side or corner.

Consequently, it is a basic assumption of the design method described in this paper that small friction pile groups fail when the corner or edge piles break loose by shear failure from the bulbs of pressure that would otherwise distribute the pile loads safely. Larger groups than those tested may settle as a result of consolidation due to vertical pressures under the center of the group and may be investigated for this condition by the formulas for vertical pressure (Eqs. 3*c* and 4*b*). However, in computing the load-carrying capacity of any arrangement of piles, the group should first be investigated against failure in shear along the outer piles.

For the purpose of illustrating the contribution of shear from each pile in a group to the shear on the outer piles, and the further fact that the shear at midheight of a corner pile of a group is most critical, the shearing stresses under failure loads are shown in Fig. 8(*a*) around a single pile, a group of nine piles, and a group of sixteen piles, computing these shearing stresses at the butt, the tip, midheight, and the two quarter points, and using $R_c = 1.5$. In the computations of the failure loads on the piles in these various groups, an average shearing strength of 750 lb per sq ft at failure of a single pile was used for convenience of computation. It will be noted that the shearing stresses, in pounds per square foot of embedded surface on the single pile, increase slowly from butt to tip, being larger toward the tip because of the better shear value of the soil there due to internal friction. It will also be noted on the 9-pile and 16-pile groups of Fig. 8(*a*) that the vertical shears shown around the outside piles in no case exceed the vertical shears at corresponding heights on a single pile, and that, as the number of piles in the group increases, the load per pile must decrease in order to satisfy this condition, owing to the contributions of all other piles to the shears on each outside pile. The critical point around the perimeter for groups of this size is seen to be at midheight of the outside surface of the corner pile, and, if the assumed shearing value of 750 lb per sq ft at the midheight of this pile is exceeded, failure will occur and spread progressively to the less critically stressed points around the group perimeter.

DETERMINATION OF SHEAR-FAILURE LOAD OF A GROUP

A method of determining the shear-failure load of a group of piles, using the derived formula (Eq. 2*c*), would consist, first, of loading a single pile to failure, as determined by the load at which the pile settlement under small additional increments of load would increase rapidly and the pile would no longer come to rest. This test load divided by the contact area is the average skin friction, which equals the shear-failure value at midheight of a pile. A group is assumed to fail by shear at this test-determined value per square foot along a plane intersecting the outer surface of a corner pile, and drawn approximately normal to the line connecting this corner pile with the center of gravity of the group. A load P is assumed on each pile of the group arrangement to be investigated. The contribution of each pile in the group to the midheight shear of the corner or critical pile is found by using the general shear formula (Eq. 2c) and multiplying the contribution of each of the other piles by the sine of the angle of action with the diagonal plane of failure. When these contributions from all piles in terms of a load P per pile are added to the usual midheight shear on the surface of the corner pile (which is equal to P divided by its penetrated contact area), a decimal number is obtained, multiplied by P. The shear-failure value per square foot is divided by this decimal number, and the quotient is the failure load P per pile.

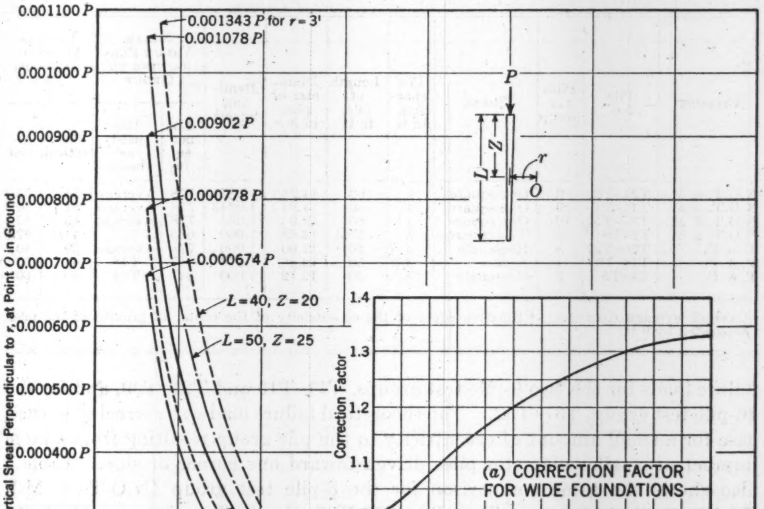

FIG. 9.—VERTICAL SHEARS AROUND FRICTION PILES, AT MIDHEIGHT (R_c = 1.5)

To facilitate the computation, curves have been drawn in Fig. 9, plotting the shear formula for R_c = 1.5 for various actual pile lengths from 40 ft to 80 ft, giving the shear at midheight of a pile at any radius from the pile. From these curves it is possible to read directly the fractional part of P contributed as shear by any pile in the group to the shear on the critical pile at the corner, on a plane normal to the line connecting the two piles.

In order to demonstrate the accuracy of the use of these derived formulas, Table 5 has been compiled to show the comparison of theoretical and actual failure loads for the two 9-pile test groups, T11–T19 and T21–T29, and for the 16-pile test group, T37–T52. The theoretical failure load was corrected in each case for a small amount of eccentricity in the pile group resulting from a large number of smaller diameter piles driven toward one corner or side. Table 5 also shows the same comparison for the 8-pile test group (N.O.T. & M.), T2–T9; 8-pile test group (T. & P.), T20–T27; the 4-pile test group (T. & P.) T14–T17; and 2-pile test group (T. & P.), T4 and T5.

[c] Separated by 9 ft.

Unfortunately individual piles were not driven and tested to failure adjacent to all of the groups because time and available funds were both limited, and, in computing the carrying capacity of those groups where no single pile test was made nearby, the average shear value of 778 lb per sq ft of all single piles tested to failure was used. On the other hand, where single piles had been driven and tested to failure near some of the smaller groups, the actual shear values of these single piles were used in computing the theoretical failure load. It will be noted that theoretical failure loads computed on this basis checked very closely with the actual failure loads.

MODIFICATIONS OF METHOD FOR LARGE GROUPS

Since each pile distributes its load outward and downward, it is evident that, as the group size increases, the point of critical shear on the outer piles will tend to move downward. From computations of various sizes and arrangements of groups, it has been found that, where the side of a square group is more than one third of the length of the piles, the critical shear on the corner piles occurs lower than the midheight of the pile. Thus, the failure load determined from curves plotted for midheight computations (Fig. 9(*b*)) should be divided by the factors in Fig. 9(*a*).

COMPUTATION OF SAFE LOADS

This method primarily establishes the failure load per pile of a group in shear. In the actual design of structures supported on friction piles, the working load chosen per pile should provide ample safety factors (1) against possible shear failure, and (2) against excessive settlements from vertical pressures, giving due regard to the relative proportions of dead, live, and dynamic loads. The dead load is the constant load that may produce excessive settlement over long periods of time without necessarily resulting in a shear or total failure. It is probable that a working load, or dead plus live load, may be chosen some-

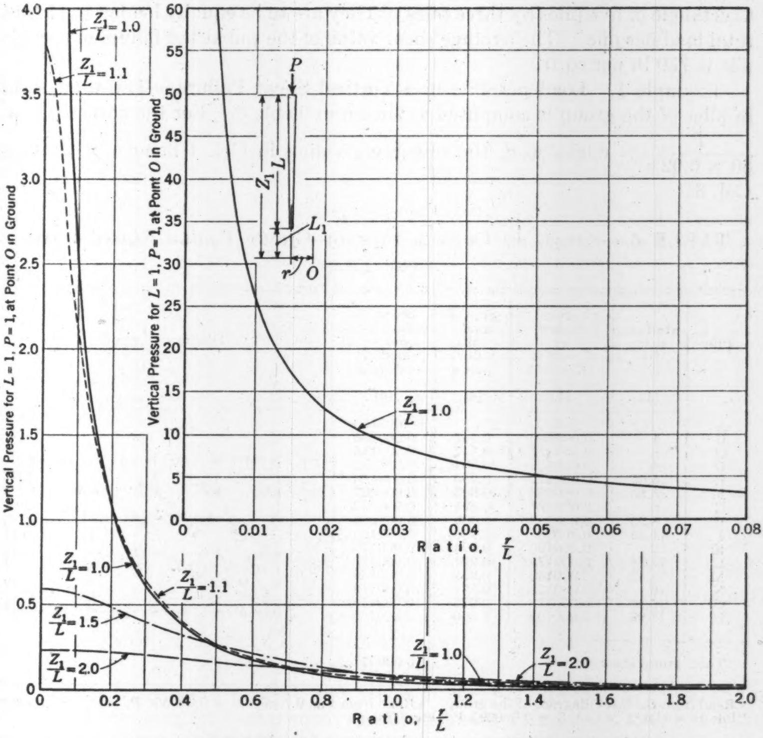

FIG. 10.—UNIT VERTICAL PRESSURES BENEATH A SINGLE FRICTION PILE ($L = 1$; $P = 1$; $R_s = 1.5$)

what closer to the shear-failure load in large groups than in small groups, because of the relatively sluggish failure of larger groups as illustrated by the behavior of the 16-pile group under test.

Illustrative Problem.—The following example illustrates the manner in which this pile theory is applied to an actual problem of computing the failure loads and pressures of a 15-pile group. The calculations of vertical pressures were facilitated by the use of the curves of Fig. 10, in which the vertical pressure formulas have been plotted for a pile length $L = 1$ and load $P = 1$.

In this problem, fifteen 60-ft piles, with a specified minimum tip diameter of 8 in. and a minimum butt diameter of 14 in., are laid out at 4-ft centers in a rectangle of five piles by three piles. They are to be equally loaded to 15 tons total load per pile. The average shear value of the soil at the failure of a single pile is 750 lb per sq ft.

Example 1. Load per Pile in a Vertical Shear Failure.—The total shear in piles of the group is computed as shown in Table 6. For the corner pile A, $\frac{P}{60 \times 0.92\,\pi} = 0.005780\,P$, the remaining values in Col. 4 being Col. 2 times Col. 3.

Total group shear =				0.009071 P	

[a] Read from the inset diagram of the group. [b] Read from Fig. 9, "pile B = 0.000660 P," etc. [c] Compute: "Pile B = Col. 2 × Col. 3 = 0.000295 P," etc. (Col. 4).

From the total group shear in Table 6, the failure load P per pile equals

$$\frac{750 \text{ lb per sq ft (failure shear)}}{0.009071} = 82{,}700 \text{ lb} = 41.4 \text{ tons}.$$

(In the inset diagram of Table 6 the failure plane is drawn normal to the line connecting the corner pile with the center of the group—a 45° plane gives almost the same results.)

Example 2. Vertical Pressures Beneath the Group Under 15 Tons per Pile.—In Table 7, the inset diagram shows the group dimensions reduced to proportional parts of L ($= 60$ ft), with radial distances from the center pile to each other pile. The table shows the method and results of the computation of vertical pressures.

[a] The actual pressures in last column are equal to units in preceding column multiplied by $15/60^2$.

Two important conclusions are to be noted in the solutions of Examples 1 and 2: First, that the failure load per pile, of the 15-pile group, is slightly greater than that of the approximately equivalent 16-pile square group of Fig. 8(a); and second, that the vertical pressures under the center pile of the 15-pile group are slightly less than those beneath the interior piles of the 16-pile square group of Fig. 8(b) if it is loaded to 15 tons per pile.

These conclusions suggest that tables of shear-failure load per pile, and of pressures beneath groups for square groups of many dimensions, may be a useful guide to design. Tables 8 and 9 have been prepared with that purpose in mind. Table 8 has been prepared for a shear-failure value of 750 lb per sq ft from which results may be proportioned for other values; and Table 9 has been prepared for 10 tons per pile, from which results may be proportioned for other loads. The tables should be used subject to the following rules:

(1) A rectangular or circular group will fail in shear at a larger load per pile than a square group containing the same number of piles.

(2) A rectangular group will have smaller vertical pressures and a circular group will have larger vertical pressures than a square group containing the same number of piles.

[a] Governed by shear summation at midheight of corner pile; all others governed by shear summation at some point below midheight of corner pile.

PRACTICAL APPLICATION OF THIS METHOD TO DESIGN

On the basis of the preceding data, the following would be the design procedure:

(1) Make sufficient borings at the site to establish the approximate uniformity of the soils over the entire area being considered, and to establish further the fact that a firm stratum for the support of point bearing piles is not economically accessible.

(2) Drive a test pile of about the length contemplated to be used in the design, and if the number of hammer blows per foot increases only gradually with increased penetration, the pile will be a friction pile, distributing load approximately in the manner suggested by this pile theory.[a] More than one test pile may be used to sample the area thoroughly.

(3) Load the test pile, by increments, to failure, which will be indicated by a sharp increase in settlement that does not cease with time, and which should result in at least several inches of settlement. From this failure load, the shear-failure value, in pounds per square foot, may be computed by dividing by the penetrated contact area.

(4) With this shear value in mind determine, by an examination of Table 8, approximately what the failure load per pile will be for the approximate number of piles required, and select a working load per pile that provides an ample safety factor consistent with the group size and the loading characteristics. For an unusual group, the determination of failure load may be made more precisely by the method given in Example 1.

(5) Find the approximate vertical pressures beneath the center of the group, under the working load chosen per pile, by examination of Table 9 (some interpolation may be necessary). If the pressures seem dangerous, or if the group is unusual, a more precise calculation may be made by the method given in Example 2.

(6) If consolidometer tests have been made on samples of the soil beneath and around the piles, it will be possible to compute, from the vertical pressures determined by use of the formulas and curves, a theoretical maximum settlement of the pile tops along the vertical center line of the footing under the working load. This theoretical settlement cannot be realized fully, especially in piles supporting a stiff pier base where the stiffness of the footing will restrict

settlements because of the lower pressures existing under the edges of the footing. If the area under a large building is thought of as one large footing in sections, however, the indicated center settlement may be realized.

MODIFICATION OF PRESSURE DISTRIBUTION DUE TO VARIATION IN MATERIALS

The materials encountered on the Morganza Floodway are believed to distribute loads in a manner representative of most true friction pile foundations. If the materials were to grow progressively denser with increased penetration, the distribution of pile load to the soil would become greater toward the tip, of course, and the effect of this could be estimated by reducing the value of R_c in all the formulas from the value of 1.5 used in this paper. Ratio $R_c = 1$ would represent a pile with uniform load per foot, and $R_c = 0$ would represent a distribution of load increasing from zero at the butt to a maximum value at the tip.

As the materials would become denser and denser toward the tip, the reduction in pile strength due to grouping would become progressively less pronounced until, with pile tips bearing on rock, the permissible load per pile in a group would be equal to the permissible load on a single pile.

MODIFICATION OF RESULTS BECAUSE OF OTHER THAN BOUSSINESQ DISTRIBUTION

The Boussinesq distribution of stress is always downward from a point of load, and has been used with success in determining pressures beneath many buried foundations. Professor Mindlin's formulas[2] indicate a stress distribution upward by tension as well as downward by compression from a point load buried in the ground. D. M. Burmister, Assoc. M. Am. Soc. C. E., has presented the Mindlin formulas in usable form for pile foundations,[3] as reproduced in Table 10.

From Table 10(*a*), showing stress distribution around a pure friction pile with uniform load per linear foot, it has been possible to compute a curve of vertical shears around a pile at midheight. In Fig. 11 this curve is shown in comparison with the corresponding curve from the general shear formula (Eq. 2*c*) derived in this paper, using $R_c = 1.5$, and with a curve from the same formula using $R_c = 1$ for the condition of uniform load per foot of pile.

The comparative tendency of the Mindlin distribution is to reduce pressures beneath the pile and increase the shears around the pile, thus throwing more load into distant piles of a group and making group action more dangerous than the Boussinesq distribution would indicate.

Since the curve for $R_c = 1.5$ under Boussinesq distribution checks the pile tests more closely than does the curve for Mindlin distribution, it would seem that timber friction piles distribute load more nearly in accordance with the Boussinesq formulas.

IMPLICATIONS OF THIS THEORY OF FRICTION PILE BEHAVIOR

If this theory is correct in stating that shear failure occurs through the building up of critical shear stresses on the corner piles of square or rectangular groups, it would follow logically that a more efficient grouping arrangement against shear failure could be obtained by eliminating corner piles through the use of octagonal footings containing the same number of piles.

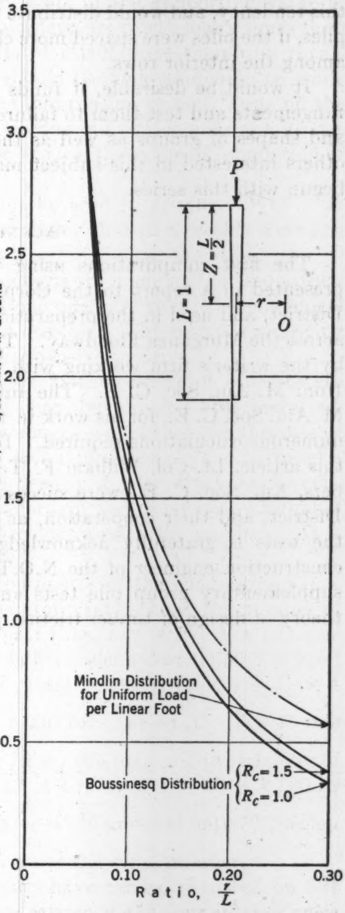

FIG. 11.—COMPARISON OF UNIT VERTICAL SHEARS AROUND A SINGLE FRICTION PILE BY BOUSSINESQ AND MINDLIN DISTRIBUTIONS (AT MIDHEIGHT OF PILE)

---

[3] "Proceedings of the Purdue Conference on Soil Mechanics and Its Applications," Purdue Univ., Lafayette, Ind., September 2 to 6, 1940, p. 339 (citing also "Stress Distribution Around a Loaded Pile," by J. Ruderman, Thesis No. 500 submitted to the Dept. of Civ. Eng., Columbia Univ., New York, N. Y., in 1939, in partial fulfilment of the requirements for the degree of Master of Science).

Where a large group of friction piles supports a stiff pier base, some redistribution of pile loads toward the edges from those calculated will take place in order that the settlement of the edge piles due to vertical pressures may become equal to the settlement of the center piles. It would be in accord with this tendency, and would distribute the pier load more equally to the individual piles, if the piles were spaced more closely in the exterior rows of the group than among the interior rows.

It would be desirable, if funds were available, to make various group arrangements and test them to failure so as to have additional test data on sizes and shapes of groups as well as the most efficient spacing. It is hoped that others interested in this subject may be able to continue the tests that were begun with this series.

ACKNOWLEDGMENTS

The first computations using the formulas derived in this paper were presented in a report to the Corps of Engineers, U. S. Army, New Orleans District, and used in the preparation of designs for proposed railway crossings across the Morganza Floodway. The report was presented in December, 1940, by the writer's firm working with that of J. F. Coleman, Past-President and Hon. M. Am. Soc. C. E. The author is indebted to Harry J. Engel, Assoc. M. Am. Soc. C. E., for his work in the derivation of the equations used and the numerous calculations required. During the progress of the pile tests used in this article, Lt.-Col. William F. Tompkins and Lt.-Col. Clark Kittrell, Members, Am. Soc. C. E., were successive district engineers for the New Orleans District, and their cooperation, as well as that of their assistants, in making the tests is gratefully acknowledged. Roscoe Owen, M. Am. Soc. C. E., construction engineer of the N.O.T. & M. Railway Company, supervised the supplementary group pile tests and has made valuable comments upon the theory of design of timber friction pile foundations presented in this paper.

DISCUSSION

E. H. CONNOR,[4] M. AM. SOC. C. E.—The tests of the supporting value of piles in various groups, as reported by Mr. Masters, are worth many times their cost, and the formulas deduced and results of calculations therefrom reveal many interesting facts. Many more tests should be made and could be made with a saving of millions of dollars from the information gained: Tests on the spacing of piles in groups, on the result of leaving out center piles of a group, on the supporting values in sand in the river bed, on the value of foundation of piles driven on a batter, etc.

Some engineers specify that a jet cannot be used in driving. Why? It would save money in many cases. Do they know that in a week's time one pile driven in sand or clay would support a lesser load than the other.

It is evident that many pile-foundation designs are made on the assumption that 60 piles will carry 60 times as much as one pile, and that it is economical to crowd these piles into as small an area as possible. The result is a spacing so close that the piles are very difficult and expensive to drive.

Of course, the volume and the cost of the footing course of concrete are reduced. The strength of the foundation may be reduced still more. A proper spacing of piles to secure the same strength would increase the cost of concrete but reduce the cost of piles. The economical design then becomes a question of unit costs of concrete and piles, length of piles, thickness of concrete base or sealing course. The cost of cofferdam and excavation also must be considered; but the proper design now becomes a scientific problem. It is still not an exact science.

The writer often has thought that the perimeter of the entire group in a certain location determined the power of the group rather than the number of piles, if the piles were not spaced farther apart than, say, 4 ft. For instance (see Table 1(*c*)), a group of nine piles T11–19 failed under a load of $(56.3 \times 9 =)$ 507 tons. Assuming that the perimeter of group length is $(2 \times 4 + 1) \times 4 \times 59.7 = 2{,}149$ sq ft, the shear is $\frac{507}{2{,}149} = 0.236$ tons per sq ft. The 16-pile group T37 to 52 failed under load of $(42.9 \times 16 =)$ 686 tons. The perimeter of the group multiplied by the penetration is $(3 \times 4 + 1) \times 4 \times 60 = 3{,}120$ sq ft, and the shear is $\frac{686}{3{,}120} = 0.220$ tons per sq ft—a difference of only 7%, which amount could easily exist in two similar groups of the same number.

How much would the group of sixteen piles have carried if spaced on 3-ft centers? How much would this group have carried if the four interior piles had been omitted?

Another feature has come to the attention of many. By standing unloaded a few days after driving, a pile will carry an increased load. Four piles were driven in San Francisco Bay to support a derrick. They were 90 ft long and penetrated about 25 ft of water and 55 ft of clay. They drove easily and did not show greatly increased resistance to driving as the penetration increased.

---

[4] Vice-Pres. and Cons. Engr., Mo. Val. Bridge & Iron Co., Leavenworth, Kans.

It was suggested that the length of the piles be increased to 120 ft. After waiting two days, a single-acting steam hammer (5,000-lb ram, 36-in. stroke) could not move the 90-ft piles. These lengths were used for a year without settlement.

In 1900, the writer's firm built a creosoted pile trestle across Biloxi Bay. The piles drove easily in the mud—too easily. They would not support much more than a heavy hammer. The contractor was alarmed. The specifications required that the causeway carry a load of 100 lb per sq ft. It was completed and several panels loaded to 100 lb without any settlement and the causeway served the public nearly thirty years.

In 1912 the Kansas City Terminal Railway Company made tests of concrete piles driven in dry loam, testing them immediately after driving. Some were tapered; some had parallel sides. The tapered piles carry considerably more than those with parallel sides but they are difficult to keep plumb and they yield more readily to side movement from obstructions struck while driving.

From the contractor's point of view, one other point in spacing piles should be given more consideration; that is, the distance from the outside edge of the concrete base to the center of the outside row of piles. This is usually shown on the plans as 18 in. In a deep excavation or cofferdam, wales at least 12 in. wide are needed. A 5,000-lb, single-acting steam hammer (36-in. stroke) has an over-all clearance of 40 in. requiring 36 in., with 4-in. clearance, from the center of the outside pile to the inside of sheet piles unless a follower is used.

Glenn B. Woodruff,[5] M. Am. Soc. C. E.—Many engineers have been aware of the general principles demonstrated by this paper. The thanks of the profession are due the author for presenting the results of these tests in a manner that gives a mathematical statement of these principles.

Although Table 5 shows a remarkable agreement between theoretical and actual results, the author probably will agree that delta deposits are generally so heterogeneous that extreme precision in predicting results is unwarranted. It appears permissible therefore to simplify several of the equations by eliminating terms that will have minor influence on the results.

The load tests were made shortly after the piles were driven. Possibly, over a long period of years, the distribution of the loads from the piles to the surrounding soil will change materially. In most silty soils, the process of soil consolidation under its own weight is still continuing. If the strata near the surface are settling, these strata, rather than taking load from the piles, will be supported partly by the piles and will add to the pile load. It will be difficult to separate the results of this action from the settlements resulting from the consolidation of the strata below the pile tips, but it is to be hoped that the owners of the structures to be built will arrange for such a record of settlements under piers of varying size that certain conclusions can be drawn.

Tables 8 and 9 show clearly the advantages of wide pile spacing. This wide spacing has the disadvantage that larger, and consequently heavier, footings are required to distribute the superstructure loads to the piles. In some cases, it becomes advisable to use battered piles to combine the advantages of a small pile cap and a wide distribution of the load. In this way, each of the piles in a comparatively large cluster may be made to approach the load-carrying capacity of a single pile.

JACOB FELD,[6] M. AM. SOC. C. E.—A complete solution of the subject of friction piles has been presented in this paper, and the author is to be complimented for his derivation of empirical tables for practical use in design.

The average frictional resistance along the surface of a single pile at failure for timber piles (Table 4) is given as 778 lb per sq ft, as against 558 for parallel-sided concrete piles. The discrepancy is merely the result of an assumption. Shear failure in the case of either wood or concrete piles is not along the pile surface but along a soil surface, formed by the adhesion of some soil to the pile. In the case of tapered wood piles, the proper surface area seems to be governed by the maximum pile diameter, not by the average. Certainly at failure, the soil directly below the tapered surface is compressed sufficiently to act as part of the pile. Table 11 shows the data of Table 4(*a*) with such adjustment; the average soil friction for the wood piles is 600 lb per sq ft of cylinder surface, with the butt diameter.

TABLE 11.—SKIN FRICTIONS, INDIVIDUAL, TAPERED, TIMBER PILES (SEE TABLE 4(*a*))

Pile No.	Length (ft)	Load at failure (tons)	DIAMETERS (IN.)		SKIN FRICTION, IN LB PER SQ FT	
			Tip	Butt	Average diameter	Maximum diameter
T1	52	66.5	8.5	17.5	685	560
T10	59.5	96.5	11.5	17.75	900	700
T20	85	100	8.0	17.5	680	500
T34	83	110	8.5	16.75	777	600
T18	50.5	70	8.5	16.5	847	640
Average					778	600

Since the minimum value occurs with the minimum tip and the maximum value occurs with the maximum tip, there is certainly some variation with tip size. The number of test values is not sufficient to draw more definite conclusions.

A group of friction piles in itself is a means of transferring loads to lower soil layers, very much in the manner of a spread footing. The similarity of the two rules in Example 2 with the conclusions drawn from tests with spread footings, therefore, is not surprising. Only by exposure of loaded surface to soil not carrying its full capacity can loads be carried safely.

The writer has used a very rough rule for the ratio of load-carrying capacity of a group of piles to that of a single pile. Since it seems to have some relation to the result presented in this paper, the rule is given herein. The value of a pile in a group is the value of a single pile less one sixteenth for each adjacent diagonal or row pile (see Table 12). In view of the unknown relative effects of tip area and length upon the unit bearing value of a pile, the suggested reduction in pile values of a group is an easy approximation. A pile fully enclosed in a group, as the center pile in a square array of nine piles, has a value of 50% of a single pile. A minimum pile spacing distance is assumed.

This method, applied to the author's examples in Table 6 and Fig. 8, gives values of 10.25 and 10.75 equivalent single pile units for the 15-pile and 16-pile groups. This would indicate that in the 15-pile group an individual pile would fail at about 60 tons, if the average failure load equals 41.4 tons. This value is consistent with the individual failure tests. Fair agreement is also found with the data in Table 5.

[a] Omitting Center Pile of the 9-Pile Cluster Does Not Affect Bearing Value of the Cluster.

G. G. GREULICH,[7] ASSOC. M. AM. SOC. C. E.—Careful and adequate driving and load tests made preliminary to the final preparation of a design are described in this paper. It is apparent that, after reviewing all available recorded data, previously expounded theories and formulas were expanded and modified in an intelligent manner so as to be theoretically compatible with the test results. The closeness of the approximations is shown by Table 5. However, the close agreement shown in the table may be due, in a large measure, to the exceptionally uniform soil conditions prevailing in this portion of the Lower Mississippi Valley. In areas where more heterogeneous soils may be encountered, it is doubted whether such close agreement would be found.

The theoretical failure loads given in Table 5 are remarkably close to the actual failure loads and demonstrate that, on occasion, the law of averages will take care of widely varying factors. Reference to Table 1 shows that there is very little relationship between the hammer blows for the last foot of penetration and the actual skin friction values developed at failure. For example, in the T. & P. tests, pile T18, requiring 25 blows for the last foot of 50.5 ft of penetration, shows a skin friction value of 847 lb per sq ft, as compared with 610 lb per sq ft for T14–T17, where the number of blows for the last foot of approximately the same length of penetration (50 ft) was 27, or two more than for the much higher load developed by the first pile. Reference to the N. O. T. & M. tests, pile T34, requiring 8 blows for the last foot of 83 ft of penetration, shows a skin friction value of 777 lb per sq ft, as compared with 680 lb per sq ft for T20, where the number of blows for the last foot of 85 ft of penetration was 30.

---

[7] Sales Representative, Specialty Sales Div., Carnegie-Illinois Steel Corp., Pittsburgh, Pa.

In spite of the wide variation of skin friction values for individual piles, the average value from Table 4 apparently gave exceptionally accurate results when used by Mr. Masters in predicting theoretical group behavior. This is especially notable in view of the normal and often wide variation found in the shape of timber piles and their behavior in driving when driven in isolated groups. The writer wonders if this method will prove as accurate when applied to groups at other locations. Only additional similar test data will develop this point. In the meantime, it has been demonstrated again that, having access to carefully recorded test data, it is possible to develop rules or formulas that do give reasonable results for any areas of ground which are comprehensively covered by test data.

In the writer's opinion, Mr. Masters has done a great service to the profession by the incorporation of Table 8. Perusal of this table should give any practicing engineer a vivid picture of the rapid reduction in load capacities of piles when used closely spaced in large groups. This table throws light on a remark made some years back by an elderly engineer whose name the writer cannot recall. In his practice, he had built a number of swing bridges with the main center pier founded on piles. In spite of the fact that the timber piles he ordinarily used tested satisfactorily in clusters of four for safe loads of 16 to 18 tons per pile, he found that, in order to keep settlements within workable limits for his movable structures, he could not load the piles to more than 7.5 to 8 tons.

Referring to Table 8, it will be noted that, for 2.5-ft spacing of 40-ft piles, the failure load for clusters of four is computed as 32 tons per pile. On such a pile, a 16-ton to 18-ton load might ordinarily be considered a safe working load. Going on down the tabulation to 16.5-ton load per pile, which would represent a safe load of 7.5 to 8 tons, it is noted that a group of 49 piles would have this theoretical capacity per pile:

> Multiplying 49 piles by 6.25 sq ft of contributory area, on 2.5-ft spacing, the resulting gross area is approximately 306 sq ft.

This area could well have been the area of the main piers of some of the early, light, swing bridges of this type which were approximately 20 ft in diameter. As stated before, it is believed that this paper gives a vivid explanation of the elderly engineer's remarks, and emphasizes the necessity for drastic reduction in assumed design loads for individual friction piles when closely spaced in large clusters.

G. S. PAXSON,[8] ASSOC. M. AM. SOC. C. E.—There is probably no part of structural design less understood than foundations, especially foundations supported by friction piles. For many years, it has been known that the value of a group of piles was not the sum of the values of the individual piles taken separately. The method of design proposed by Mr. Masters provides a quantitative solution of the problem. The remarkable correspondence between the theoretical and actual loads at failure in the Morganza Floodway tests gives great support to the proposed method as a practical design tool.

---

[8] Bridge Engr., State Highway Comm., Salem, Ore.

The writer was particularly interested in the approach that the paper provides to the question of piles versus spread footings on cohesive soils. There are many contradictory statements in current engineering literature on this subject, but, so far as the writer knows, no quantitative comparison has been given.

In Fig. 12, showing the approximate vertical pressure, q_v, contours are given for a foundation supported on piles and for the same foundation resting directly on the soil. The pressure contours on the left-hand side of the figure show the pressures in pounds per square foot for the foundation resting directly on the soil, whereas those on the right-hand side show the pressures under a foundation supported by piles. The foundation chosen for the example was a square, 12 ft on a side. For the pile foundation, 16 piles were used. The piles were symmetrically placed, spaced at 3 ft on centers with 1.5 ft allowed between the pile centers of the outside rows and the edges of the foundation. A load of 10 tons per pile and a pile penetration of 40 ft below the bottom of the foundation were assumed. The piles were assumed to have a 14-in. butt and an 8-in. tip. In the formulas for pressure, a value of $R_c = 1.5$ was used. The spread foundation was the same size as the pile foundation and carried the same total load, 160 tons.

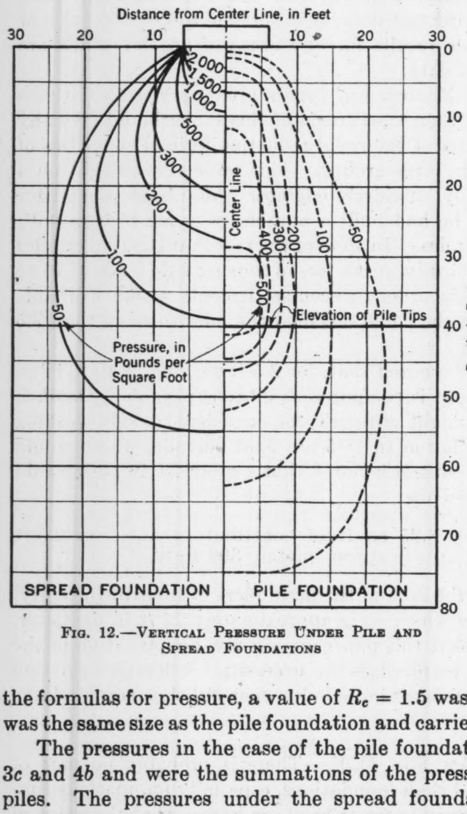

Fig. 12.—Vertical Pressure Under Pile and Spread Foundations

The pressures in the case of the pile foundation were computed from Eqs. 3*c* and 4*b* and were the summations of the pressures contributed by all of the piles. The pressures under the spread foundation were computed by the Boussinesq formula applied to subdivisions of the foundation area. The pressure contours are those in a vertical plane passing through the center of the foundation and perpendicular to the sides. It should be noted that this plane does not pass through any pile and does not show the local pressure concentrations close to the peripheries of the piles.

It is interesting to note the differences in pressure distribution. Under the assumed loading, the greatest pressure under the pile foundation does not exceed 600 lb per sq ft and is confined to a zone around the lower 10 ft of the pile lengths, whereas, under the spread foundation, the pressures reach the unit load on the slab (2,220 lb per sq ft) with the higher pressures near the ground surface. In the usual case of a fairly uniform soil, it is of advantage to transfer the loads to considerable depths below the surface as soil samples generally will show a decreasing voids ratio with increasing depth. There are other cases, of course, in which the surface stratum is better than the underlying material. Under such a condition, a pile foundation might show more total settlement than a spread foundation of the same size.

The consolidation of soil held between piles that are spaced reasonably close together is undoubtedly a complicated procedure and probably not susceptible of analysis. It is possible that the entire block settles as a unit and that the pressure at the pile tips is the pressure of the foundation slab, less the pressure transferred to the surrounding soil by the outside rows of piles. Since, in general, the soil consolidation is proportional to the logarithm of the applied pressure, it would seem that piles in the ordinary soil formation would decrease the total settlement of a foundation considerably.

RAYMOND D. MINDLIN,[9] ASSOC. M. AM. SOC. C. E.—An unfortunate error made by the author invalidates most of the conclusions drawn from the mathematical portion of his investigation. A solution of the equations of elasticity, known as the Boussinesq solution, is used in this paper, in an attempt to establish a rational estimate of the stress distribution in the soil around a friction pile. The applicability of the classical theory of elasticity to stresses in soils is debatable, but may be allowed as a first approximation on the basis that no better theory exists. However, once this barrier is passed and the investigation enters the realm of elasticity theory, it is not permissible to violate the mathematical and physical laws which immediately become effective.

It has been observed before[10] that, when the Boussinesq solution is integrated along a line parallel to the direction of the applied force, as the author has done, additional distributed loading is automatically introduced on the surface. The resulting stresses in the interior of the body are then those due not only to the line load penetrating into the body, but also to the distributed surface load.

The author implies that his formulas (Eq. 2*c*, for example) represent stresses at depth Z due to the distribution of delivered load P' (Eq. 2*a*) extending from the butt to the tip of a pile of length L. He should state, at this point, that the form of P' is either an assumption, or is based on experimental or theoretical results which he should supply. (Actually, the determination of P' is the most difficult part of the problem.) Furthermore, Eq. 2*c* gives, in fact, the distribution of s_v at (and only at), a depth Z due to (1) that part of P' (and only that part) between the surface and depth Z, plus (2) a surface distribution of s_v and q_v.

---

[9] Asst. Prof., Civ. Eng., Columbia Univ., New York, N. Y.

[10] "On the Distribution of Stress Around a Pile," by R. D. Mindlin, discussion of papers, Section E—Stress Distribution in Soils, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Cambridge, Mass., Vol. III, 1937.

The fact that the surface distribution exists in the author's solution is masked by the fact that, in Eq. 2c, the symbol Z represents both the coordinate of the plane on which s_v is to be calculated and the depth to which the line of load extends. If Z is allowed to approach zero in Eqs. 2c and 3c, s_v and q_v also approach zero; but this is not because no surface loading s_v (or q_v) is implied by the author's integration. Because of the dual meaning of Z, one cannot move the plane on which the stress is to be examined without changing the length of the line of load. Thus, if it is desired to use Eq. 2c or Eq. 3c to investigate the stress at the surface, one will, at the same time, automatically reduce the length of the line of load to zero (that is, the entire solid is unloaded), resulting in no stresses in the solid at all, and, of course, no stresses at the surface. The expression for s_v the author would have found, if he had prosecuted his incorrect theory rigorously, is (confining attention to the case $R_c = 1$, for simplicity):

$$s_v = \frac{P\,r}{2\,\pi\,L}\left\{\frac{Z^3}{r^2\,[r^2 + Z^2]^{1.5}} - \frac{(Z - Z')^3}{r^2\,[r^2 + (Z - Z')^2]^{1.5}}\right. \cdots\cdots\cdots (5)$$

in which Z is the distance below the surface of any point, and Z' is the distance, below the surface, to which the line of load extends. It is then seen that if no distinction is made between Z and Z', the author's result is obtained. In Eq. 5, however, it is seen that the stress does not vanish at the surface ($Z = 0$). Hence the stress distribution found by applying the Boussinesq solution is one due to a line distribution of load, plus a surface distribution which does not actually exist. The author's formulas represent only a part of the results to be expected from integration of the Boussinesq solution, and, since the Boussinesq solution does not apply to his case, even the part that he gives is incorrect.

Furthermore, in Eq. 5, Z' should be taken equal to L (the length of the pile); otherwise, if it is taken equal to Z, it is assumed incorrectly (and the author has implicitly done this) that the portion of the pile extending below the plane on which the stress is calculated does not affect the stress on that plane.

The author refers to a solution of the elasticity equations by the writer[2] and states that it does not check the test results quoted in the author's paper. This is not surprising on several counts, but chiefly because the solution and the tests do not deal with the same problem. The writer's solution is for the stresses due to a force applied at a point in the interior of a semi-infinite elastic solid, just as the Boussinesq solution is for a force at a point on the surface of the semi-infinite solid. Neither solution deals directly with stresses due to line distributions of forces, although both may be extended to such cases, by integration, with the important reservation that the Boussinesq solution is restricted to loads distributed on the surface of the solid.

The author refers to a thesis by J. Ruderman as mentioned in a paper by D. M. Burmister.[3] Mr. Ruderman's work contains the correct integration for a uniform line distribution of load in the interior of the semi-infinite elastic solid. This thesis gives the results the author should have obtained for the case $R_c = 1$. Table 10(*a*) of the paper contains only a small portion of Mr. Ruderman's results and it is then stated that "From Table 10(*a*) * * * it has been possible to compute a curve of vertical shears around a pile at midheight. In Fig. 11 this curve is shown * * *." On the contrary, it is not possible to perform such a computation from the data given in Table 10(*a*), with the result that the curve in Fig. 11 designated as "Mindlin Distribution for Uniform Load per Linear Foot" is incorrect.

The author uses the principle of superposition to find the distribution of stress for a group of piles. It is important to emphasize that the distribution, along a pile, of load transfer from pile to soil, is influenced by the presence of neighboring piles, so that superposition is not strictly permissible in this case.

The real problem, for either a single pile or a group of piles, is to find the distribution, along the pile, of the load transfer from pile to soil. The remainder is comparatively simple, as long as elasticity is assumed. A study such as Mr. Ruderman's, even though an assumption as to this distribution is made at the start, is useful because information can be obtained from it that may be helpful in a more comprehensive attack on the problem. Mr. Masters, however, has produced a set of formulas whose only connection with the problem he has assigned himself is that they accidentally conform in part with his experimental data.

JOHN W. SOLOMON,[11] ESQ.—There are many interesting facts in this paper that certainly will be useful to the practicing foundation engineer. It is always worth while to inquire into the relationship between the computed failure load (bearing power) of a group of friction piles and the actual load required to produce failure. By referring to experiences with friction piles of reinforced concrete the writer proposes to demonstrate that the differences between failure loads of parallel sided and tapered piles, reported by Mr. Masters, can be explained easily. In addition, the differences in the solution proposed by Professor Mindlin[2] and the so-called Boussinesq formula can also be explained.

In the work that the writer has in mind numerous reinforced concrete friction piles were molded in the soil (cast in place) by first sinking a casing, then setting steel bars, and finally pouring concrete. The concrete was compacted by compressed air, and the casings finally removed. Such friction piles were constructed in the dried bed of a former river, and along the banks of a flowing river. The pile lengths varied from 40 ft to 50 ft, and the diameters from 16 in. to 17 in. The soil was a mixture of very fine sand, silt, and clay, with sometimes a pocket or stratum of medium sand.

Tests to failure, at the electric power station of Comines, in the northern part of France, gave skin friction determinations of 350 to 420 lb per sq ft. In the vicinity of the Alps, piles were driven for the towers of a high-tension line from Bissorte to Montmelian. Where this line crossed the River Arc, the skin friction was found to be only 320 lb per sq ft, the piles being 50 ft long, and the soil a very fine material composed of incongruent elements (mud). Some piles were tested by applying a horizontal pull at a point two thirds the height of the tower superstructure. This cantilever pull imposed compression

Jack

FIG. 13.—LOADING SETUP FOR PULLING TEST. FOR A PERFECT PULLING TEST USE JACK ON BOTH ENDS

on two piles, and tension on two piles. Deducting the point loads it was found that the piles in tension failed at smaller loads than those in compression. Similar tests with piles varying in length from 8 ft to 12 ft, of which 6 ft to 8 ft was embedded in pebbles and stones up to 6 in. diameter, developed a tensile resistance of from 60 to 65 tons. The compression of the concrete piles against the soil created some kind of a cementation of the soil. Conditions at the ground surface indicated that the area influenced by the test was a segment of an almost perfect sphere, with its center at the enlarged tip of the pile (see Fig. 13). For all practical purposes the simple theory of a tension cone was considered sufficiently accurate. For two piles adjacent to each other, the writer obtained the formula

$$K_R = \frac{l^3}{2\,(2\,L \tan \phi + D_t)^3} + \tfrac{1}{2} \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which K_R is a reduction coefficient; l is the distance between the centers of the two piles; L is the length of the pile; ϕ is the angle of the cone of failure; and D_t is the diameter of the enlarged tip of the pile.

In 1935 individual piles and groups of piles were placed for a large storehouse at Grande Couronne, near Rouen, on the River Seine. These piles were 70 ft long, driven into a solid chalk stratum. The soil above the chalk was a 25-ft to 30-ft stratum of fill and mud, overlying a stratum of sand and pebbles 6 ft or 8 ft deep, with alternating layers of fine sand and clay, 8 ft to 10 ft deep, to the level of the chalk. Twelve single piles were driven to a stand test load of 140 tons each (including the weight of the pile), and one group of nine piles, capped by a reinforced concrete slab, was tested at 1,350 tons. In all cases the load was applied by filling a box with iron pyrites. For the individual piles, in addition, a hydraulic jack was applied, and the settlement of the head of the pile was registered by two flexometers (see Fig. 14). The load was increased gently, at regular intervals, by increments of 5 tons. Precautions were taken so that the points of contact at the bottom of the loaded box were some distance from the piles, and the same precautions were made in fixing the support for the flexometers.

In the case of the pile group, the box of the pyrites was centered on the reinforced concrete caps. A load was applied by adding a constant quantity of pyrites to the box until the total of 1,350 tons had been reached. In this case, five registering flexometers, one at each corner, and one at the center, were used to record the settlement of the group. Every test proved that the load was transmitted to the soil from the pile, beginning quite close to the surface, and extending down to the tips. This was interpreted to mean that, for relatively small loads, only the friction surface of the upper part of the piles was working. The flexometer indicated an elastic contraction of the pile which was much less than could be expected under the assumption that the load, however great or small, was transmitted by the full length of the pile, regardless of the distribution formula adopted. At Grande Couronne the tip of the 70-ft pile began to "work" only after the superposed load had exceeded 50 tons. In any foundation project involving the use of piles, the test diagram of each pile and a record of the nature of the soil for the full depth of the pile are essential.

In the case of friction piles, an exact picture of the distribution of the load resistance at points adjacent to the entire depth of the pile require loading diagrams with load increments increased slowly. Cylindrical piles, driven in almost homogeneous soils, have a constant load distribution, beginning at a certain depth below the surface. Diagrams of the tests, such as these, permit the investigator to study the building up of stresses in the soil, as a pile is loaded, and thus to determine the interaction between the piles of a given group. Especially it is possible to appraise the final distribution under the failure load.

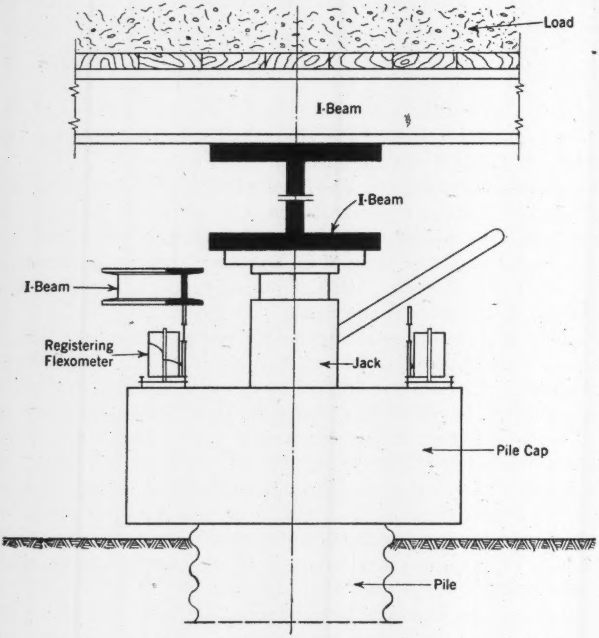

FIG. 14

The contraction of the pile itself has been neglected by Mr. Masters. Fig. 6, for example, showing shears for piles loaded to 10 tons, is not consistent with actual facts. Under only 10 tons per pile, no load would be transmitted at the tip. Eq. 2*c* was based on a positive value of the point load at the tip, greater than zero. There would be no load delivered by the tip for the piles in Fig. 6 when the applied load is 10 tons or less. The same applies to the 60-ft piles in Table 9.

Consider a friction pile in place, ready for its working load (see Fig. 15). If a load P_1 is applied, the upper length of the pile, L_1, shortens by an amount Δ_1, and the surrounding soil, for the same distance, resists that shortening.

The resulting force system represents the state of equilibrium between the work of the elastic deformation of the pile and the work of the elastic and plastic deformation of the soil. The load distribution for this depth begins at 0 at the surface, goes quickly to a value of p_1 per square foot, and continues at this almost constant value to the lower end of depth L_1, when it decreases again to practically 0.

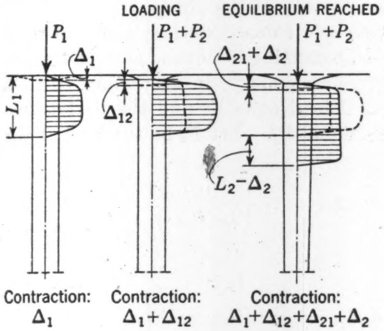

FIG. 15

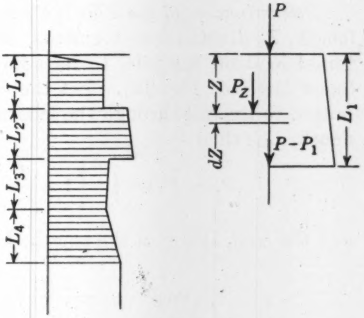

FIG. 16

The load is now increased from P_1 to a total of $P_1 + P_2$. Immediately the equilibrium between the pile and the soil is disturbed, the length L_1 is shortened to a total of $\Delta_1 + \Delta_{12}$, corresponding to the new superposed load. The hydrodynamic stresses in the soil, likewise, including the water stresses within the voids of the soil, are reduced due to the escape of water, in a period varying from a few hours or days, so that the equilibrium is further disturbed because of this condition. To reestablish equilibrium for the new load, it is necessary to add the work done by the soil surrounding the length L_2 of the pile. The final settlement for the total load corresponds to a shortening of length L_2 by Δ_2, plus a supplementary shortening of L_1 by Δ_{21}, due to the diminishing load distribution in length L_1. The load distribution, through $L_1 + L_2$, is balanced according to the same law as that applying to L_1; that is, it changes to a value greater than p_1. This sequence continues for successive increments of load increases, until $P_t = \Sigma P_i$ has made use of the entire resisting power of the pile to the tip, where $\Sigma L_i = L$, the total length of the pile. Only then will the contact between the tip of the pile and the soil have any effect, and only then will the pile settle under its applied working load.

If a load, P_c, traverses the pile for a depth, L_c, without encountering any resistance from the soil surrounding the pile in that distance, P_c can be called a free, or almost free, circulating load. This is the condition that occurs in the case of inconsistent soil (mud, etc.).

It should be borne in mind that the settlement of a pile head may be due, in addition to the shortening of the pile, to the consolidation of the soil about the pile, as well as the settlement of the pile through the soil, after the applied load has passed its critical value. The complexity of the load distribution during a test period depends upon the nature of the soil, and the rapidity with which test loads are applied or released. By using greater loads, P_t, a dynamic coefficient becomes involved, which, in turn, imposes a load distribution of its own, down along the pile.

After the load has begun to exert its influence at the tip of the pile, the load distribution is further readjusted, and then the pile continues to settle until the critical load is reached. If the load is transmitted to the pile by a jack, the pile descends in jerks, with every stroke of the pump.

Determination of the Elastic Contraction of a Pile.—Consider a pile of total length, L, divided into segments, each transmitting a certain part of the external load on the pile, to its adjacent soil segments, in accordance with a linear law (see Fig. 16). Let the external load equal P and the part transmitted to the soil through the length, L_1, equal P_1. Let P_z be the load at the depth, L_{1z}; then

$$P_z = P - \int_0^Z \left[1 + \frac{L_1 - Z}{L_1}\,(R_{c1} - 1)\right] \frac{2\,P_1\,dZ}{L_1(R_{c1} + 1)} \quad\ldots\ldots\ldots (7a)$$

and the contraction of the length, L_1, of the pile is

$$\Delta_1 = \int_0^{L_1} \frac{P - \dfrac{2\,P_1}{L_1(R_{c1} + 1)}\left[Z\,R_{c1} - \dfrac{Z^2}{2\,L_1}\,(R_{c1} - 1)\right]}{A_z\,E}\,dZ \quad\ldots\ldots\ldots (7b)$$

in which E = the modulus of elasticity of the pile, and the cross-section area at the point Z is

$$A_z = \pi\left[\frac{D_b}{2} - \frac{Z\,(D_b - D_t)}{2\,L_1}\right]^2 \quad\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

where D_b and D_t = the pile diameters at the butt and tip, respectively. The total contraction of the pile is given by a summation of the contractions, Δ_1; thus:

$$\Delta_{\text{total}} = \sum_{i=1}^{i=n} \Delta_i = \sum_{i=1}^{i=n} \int_0^{L_i}$$

$$\times \frac{P - \sum\limits_{i=1}^{i=i} P_{i-1} - \dfrac{2\,P_i}{L_i(R_{ci} + 1)}\left[Z_i\,R_{ci} - \dfrac{Z^2{}_i}{2\,L_i}\,(R_{ci} - 1)\right]}{A_{zi}\,E}\,dZ_i \quad\ldots (9)$$

In Eq. 9, P_0 equals 0, Z_i equals 0 for the butt end of L_i, and Z_i equals L_i for the tip end of L_i. If the soil surrounding the pile has one characteristic, L_i can be taken, for practical purposes, equal to 0; that is, when $i > 1$.

For a cylindrical pile with parallel sides, the total contraction is

$$\Delta = \sum_{i=1}^{i=n} \left[\frac{\left(P - \sum\limits_{i=1}^{i=i} P_{i-1}\right) L_i}{E\,A} - \frac{2\,P_i\,(R_{ci} - 1)\,L_i}{3\,(R_{ci} + 1)\,E\,A}\right] \quad\ldots\ldots (10)$$

and when n equals 1:

$$\Delta = \frac{P\,L}{E\,A}\left[\frac{2}{3} - \frac{R_c}{3\,(R_c + 1)}\right] \quad\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Typical solutions of Eq. 11 yield:

R_c	Δ
Free circulating load	$\dfrac{P\,L}{E\,A}$
0	$\dfrac{2\,P\,L}{3\,E\,A}$
1	$\dfrac{P\,L}{2\,E\,A}$
1.5	$\dfrac{7\,P\,L}{15\,E\,A}$
∞	$\dfrac{P\,L}{3\,E\,A}$

In the case of a tapered pile, the total contraction is

$$\Delta_{\text{total}} = \sum_{i=1}^{i=n} \left\{ \frac{\left(P - \sum\limits_{i=1}^{i=i} P_{i-1}\right) L_i}{\pi\,E\,\dfrac{D_{ti}\,D_{bi}}{4}} - \frac{2\,P_i\,R_{ci}\,L_i \left(\dfrac{D_{bi}}{D_{ti}} - 1 - \log_e \dfrac{D_{bi}}{D_{ti}}\right)}{\pi\,E\,(R_{ci}+1)\left(\dfrac{D_{bi}-D_{ti}}{2}\right)^2} \right.$$

$$\left. - \frac{P_i\,(R_{ci}-1)\,L_i}{\pi\,E\,(R_{ci}+1)\left(\dfrac{D_{bi}-D_{ti}}{2}\right)^3} \left[\frac{D_{ti}}{2} - \frac{\left(\dfrac{D_{bi}}{2}\right)^2}{\dfrac{D_{ti}}{2}} + 2\,\frac{D_{bi}}{2} \log_e \frac{D_{bi}}{D_{ti}} \right] \right\} \ldots (12)$$

and for $n = 1$, and $D_t = \dfrac{D_b}{m}$, the contraction becomes

$$\Delta = \frac{A(m) + B(m)\,R_c}{1 + R_c} \times \frac{P\,L}{E\,A_b} \ldots\ldots\ldots\ldots\ldots (13)$$

in which:

$$A(m) = \frac{m\,(-\,3\,m^2 + 4\,m - 1 + 2\,m^2 \log_e m)}{(m-1)^3} \ldots\ldots\ldots (14a)$$

and

$$B(m) = \frac{m\,(m^2 - 1 - 2\,m \log_e m)}{(m-1)^3} \ldots\ldots\ldots\ldots\ldots (14b)$$

The solution of these equations for representative values of m is presented in Table 13. For a given length, L_c, the load P_c is a traversing or a free, circulating load, as stated previously, and the contraction is expressed by

$$\Delta_c = \frac{m_c\,P_c\,L_c}{E\,A_{bc}} \ldots\ldots (15)$$

TABLE 13.—VALUES OF $A(m)$ AND $B(m)$

Analysis of a Loading Test Considering the Elastic Behavior of the Pile.—The part of a test diagram, which is usually neglected—the beginning of the test—is the most valuable for determining the load distribution in the soil adjacent to a pile. From the five tests presented in Table 2, test (*d*) is useless for this analysis because part of the readings are incorrect, the pile not being plumb. Test (*e*) is also useless for this analysis because the first reading was taken at 80 tons. It should be emphasized that the accuracy of bench-mark readings, using a standard construction level, is generally not sufficient to determine the elastic behavior of a pile. This error may be as high as ±0.001 ft. Pile T20, in Table 2, affords a good illustration of the load distribution during the loading period.

In analyzing Pile T20, the author has assumed that the load is transmitted to the soil through the entire length of the pile, following a linear law. Let $D_b = 17.50$ in., $D_t = 8.00$ in., and $m = 2.19$; then by Eq. 13, the elastic contraction is

$$\Delta = \frac{1.158 + 0.471\, R_c}{1 + R_c} \times \frac{P\, L}{E\, A_b} \quad \ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which $E = 1{,}400{,}000$ lb per sq in. (if E is greater, R_c is smaller); $A_b = 240.5$ sq in., and $L = 85$ ft. The values of R_c computed from Eq. 16 for test readings of Δ and P, are given in Table 14, the last column of which indicates values of R_c, for $E = 1{,}600{,}000$ lb per sq in. The negative value for R_c in Table 14, under the 15-ton load, indicates that no load distribution can be found which will transmit the load to the soil through the full length of the pile. For a load of $P = 25$ tons, a value of R_c equal to 170.0 indicates that the load transmitted to the soil is 1,170 lb per ft at the butt of the pile, and 6.89 lb per ft at the tip; under a load of $P = 25$ tons, there is practically no load transmission at the lower part of the pile, inasmuch as Δ equals 0.006 ft, which corresponds to an ultimate condition of rest. Therefore, high values of R_c, and even the value $R_c = 8.55$, for the case of $E = 1{,}600{,}000$, are impossible, even as a first approximation in the case of actual soil conditions. On the basis of Table 14, and of the intermediate reading given in Table 2, it can be stated as a practical matter that, for $E = 1{,}400{,}000$ lb per sq in., the full length of the pile does not transmit load to the soil until the load reaches 70 tons; for $E = 1{,}600{,}000$ lb per sq in., the full length of the pile does not act until $P = 50$ tons.

TABLE 14.—SOLUTIONS OF EQ. 16 TO DETERMINE R_c FOR PILE T20

P (tons)	Settlement of pile head (ft)	VALUES OF R_c	
		E = 1,400,000	E = 1,600,000
15	0.003	−10.15	−39.10
25	0.006[a]	+170.00	+8.55
30	0.008	11.05	4.20

	0.016[a]	3.21	1.70[d]
75	0.020[b]	11.05	4.20[c]
	0.024	3.21[c]	1.70[c]
	0.026[a]	2.20[d]	1.19[d]
100	0.028[b]	7.20[c]	3.21[c]
	0.030	4.58[c]	2.30[c]
	0.032	3.21[c]	1.70[c]
	0.045[a]	0.628[d]	0.254[d]

[a] Final. [b] Initial. [c] Includes the buckling effect; that is, the permanent settlement and deformation, if any, caused by the eccentricity of the load and the stiffness of the pile tip embedded in the solid sand layer. The 25-ton increment, however, did not reach the tip of the pile and the equilibrium of the pile-soil system is not yet re-established. [d] Includes the buckling effect.

The settlement readings reported by Mr. Masters were stopped too soon after unloading. Readings should have been continued for a period equal to the loading time (188 hr) or at least the period required for the load of 100 tons

—that is, 120 hr. Had this been done, the final settlement would have been 0.004 ft to 0.008 ft less, corresponding to a maximum elastic contraction of Δ varying from $(0.045 - 0.019 =)\ 0.026$ to $(0.045 - 0.015 =)\ 0.030$, for a 100-ton load. It seems to the writer that a value of $E = 1{,}600{,}000$ lb per sq in. corresponds more nearly to the actual elasticity modulus, unless the residual settlement of the pile head was actually less than could be estimated from the paper.

The load distribution for pile T20, with P less than 70 tons (or less than 50 tons), begins with a zero distribution at the ground surface, increases rapidly to a value of p_1 per square foot, which corresponds to a value of R_c very much less than 1. Then it increases gradually to the lower part of the effective length of the pile, where the value of R_{c2} varies from about m to 2, and finally decreases to zero. Static equilibrium is considered to be established, or nearly so. Eq. 16 for this condition was solved by determining the working length, L_w, corresponding to the load P, the results being tabulated in Table 15. For this analysis no information was available except the few readings listed in Table 2. With these data it was necessary to make a few assumptions in order to limit the range of possible R_c-values. For example, it was assumed that when the loading tests were applied, the dynamic stresses due to driving the pile were no longer present. Also, final equilibrium is assumed to have been attained after a few hours of practically no settlement.

TABLE 15.—SOLUTION OF EQ. 16, FOR VARIOUS EXTERNAL LOADS

Load P (tons)	Modulus of elasticity E (lb per sq in.)	Effective length L_w (ft)[b]	m	$A(m)$	$B(m)$	Final settlement[c] (ft)	R_c

65 to 70	1,400,000	81 to 83[a]	2.10	1.125	0.464	0.019–0.023	4.60–2.10

[a] 81 ft to 83 ft corresponds to the level of the sand stratum. [b] L_w is the approximate effective length of the pile distributing load P to the soil through friction. [c] Indicating a state of equilibrium. [d] Comparing the settlements for 15 and 25 tons it is evident that this value (0.0027 ft) should be even smaller.

To check the load distribution it is advisable to make an unloading test at about 30% to 50% of the failure load of the pile, just before the effective length of the pile coincides with the actual length. This was done partly for pile T10. The settlement of the pile caps should be recorded carefully from the very beginning, and the applied load should be increased slowly, and at regular intervals. In Table 2(*b*), pile T18 indicates that the entire length of the pile is effective in friction, under a load of 10 tons. It appears that the soil becomes denser below 40 ft. Pile T10, Table 2(*a*), indicates the following characteristics for $E = 1{,}400{,}000$ lb per sq in.:

Load P (tons)	Length L_w (ft)
16.5	35
31.5	45
41.5	55
45	59.5

For concrete piles the settlement can be determined at any point, although usually at midheight will be sufficient. For this purpose a steel pipe 1½ to 2 in. in diameter is embedded in the axial center of the pile to the depth at which settlement is to be observed. A free, movable rod is inserted within the pipe to the point of observation, and it is the top end of this rod that indicates the settlement. This suggests a very simple method for determining more exactly the load distribution in the soil during the progress of the test. More particularly is this true for piles driven in soils of complex and different characteristics. Only by this simple test can some of the problems in soil mechanics ever be solved.

Under the same load, P, the load distribution varies for piles of different total lengths. On a project dealing with timber friction piles, the test specimens should be in lengths varying by 10 ft—40, 50, 60, 70 ft, etc. For concrete cylindrical friction piles—that is, with parallel sides—it is sufficient for specimens to vary in 20-ft lengths—40, 60, 80 ft, etc. A qualitative description of the soil gained by studying borings, which indicates the depth of the different layers of soil, should always be available.

Table 3, Groups of Piles.—Consider a pile with a total length, L_1. The elastic contraction due to an external load, P_1 is Δ_1 and in this case, R_c is equal to R_{c1}, which, as the load approaches the failure load, is proportional to $m = \frac{D_b}{D_t}$. For a group of piles under the same circumstances, tests would show an elastic contraction, Δ_2, per pile, of $\frac{P_{1f}}{P_{gf}}\Delta_1$; the value of the external load, P_1, remaining the same. This is greater than Δ_1 and corresponds to a much smaller value of R_{c2}. In the foregoing P_{1f} is the failure load for individual piles, and P_{gf} is the failure load per pile in the group. This relationship indicates that in group piles the load distribution increases toward the tip of the pile, as may be expected. Test T10 can be compared with tests T21 to T29. The elastic contraction of the piles at the time of failure for the group is only a little smaller than that for an individual pile at failure; but even more important, if P_1 is small, and corresponds to $L_w \ll L$, then the tests show that the settlement in the group Δ_2 is from 50% to 200% larger than the expected ratio, $\frac{P_{1f}}{P_{gf}}\Delta_1$, if L_w would have equaled L.

In the two tests, P_{1f} equals 96.5 tons, and P_{gf} equals 55.3 tons. A comparison of predicted and actual measured contraction is given in Table 16.

In Table 3(*a*), group T21–T29, the effective length, L_w, is equal to the total length, L, for all loads beginning at 28 tons.

Table 4, Skin Friction of Individual Piles.—The differences in the average skin friction between concrete piles with parallel sides and tapered timber piles is less than revealed by Table 4. By adding the weight of the concrete piles (28 kips to 63 kips) the average skin friction of the latter increases to 645 lb per sq ft.

TABLE 16.—COMPARISON OF PREDICTED AND MEASURED CONTRACTIONS

Load P_1 (tons)	Contraction Δ_1 (ft)	CONTRACTION Δ_2 (FT)	
		Predicted	Measured
16.5	0.002	0.0035	0.0095[a]
31.5	0.006	0.0105	0.0163[b]

[a] Increase of 170% or more. [b] Increase of 55% or more; includes non-elastic settlement.

For the tapered piles the average skin friction at the time of failure is 853 lb per sq ft (tests T1, in which the pile was not plumbed, and T20, which was not tested to failure, were discarded from this average). The point resistance of timber piles and of concrete piles with larger tip surface was neglected. The difference between 645 and 853 corresponds to the effect of wedging action on the tapered piles. The swelling of wooden piles in the ground might also have been a factor in producing an increase of the critical load compared to that of concrete piles.

Friction Pile Theory.—The author's interpretation of test results is somewhat open to question. This entire problem is concerned with the distribution of the stresses in the soil as produced by a variably located point load in the soil. As early as 1848 Lord Kelvin[12] offered a solution of the stresses due to a point load in an indefinitely extended solid. Later Boussinesq gave his well-known solution of stresses in a semi-infinite body due to forces in the boundary.[13]

More recently, in 1936, Professor Mindlin, using the Galerkin vector, offered a solution for the distribution of stresses in a semi-infinite body, with a point load at any place in the body.[2] The latter solution was the connection between Lord Kelvin's and Boussinesq's problems. Each of these three theories is rigorously valid only for the theoretical, elastic and isotropic bodies (those that follow Hooke's law and which permit the superposition of small strains and stresses). It has been found that the Boussinesq theoretical distribution of stresses does not check for all soils by any means, and especially for cohesionless, or nearly cohesionless, bodies. In 1933 Froehlich introduced a coefficient ν (which he calls a concentration factor) varying from 3 to 6. In the Boussinesq solution ν equals 3 corresponds with a Poisson ratio of 0.5. Froehlich still adheres to the validity of the linear law.[14]

As the name indicates, the coefficient ν helps take into consideration the fact that the modulus of elasticity of certain soils, at various depths, is not constant. It also helps to concentrate stresses more around the point loads, corresponding to the difference between the hypothetical bodies used in the

Lord Kelvin, Boussinesq, and Mindlin stress distribution, and the real soil. Consider a point at *O* in the soil, and a pile driven not far from it (see Fig. 17). It is clear that the influence of the upper part of the pile, not far from the ground surface, would follow theoretically the Boussinesq law. At distances farther from the ground surface the distribution would approach more nearly that of Lord Kelvin's theory. Since the Kelvin distribution has an effect about half as great as the Boussinesq distribution in the horizontal plane containing point *O*, it is clear that by using a coefficient, R_m, the stress value at the point *O* can be determined with as good an approximation as may be desired. For example, if it is assumed that the pile distributes the load to the soil at a constant rate per linear foot, and if the Boussinesq formula is applied to the calculation of the stresses, giving each elementary load a coefficient dictated by a certain rule, then by integration, the stresses can be approximated as accurately as may be desired to the actual stresses. This is true, even if the influence of the point loads below the plane of point *O* is neglected. If the load distribution is not constant, a variable coefficient, R_m, and a load distribution, R_c, can be introduced. It is in this sense that the coefficient, R_c, used by Mr. Masters, is to be interpreted as corresponding to the coefficient, R_m, of the present discussion, and not as a load distribution along the depth of the piles.

FIG. 17.—VERTICAL SHEAR AT *O*, MIDHEIGHT (SCHEMATIC)
Mindlin Values Approximately 25% Larger for $R_c = 1$

Consequently, if point *O* is selected at the midheight horizontal plane of the piles, a value of R_m can be obtained which will yield the stresses in that plane. Another value of R_m would give stresses at another point *O* at a different depth. This is why the Mindlin stress distribution yields tensile stresses independent of the cohesion factor of the soil, and also why the shearing stresses computed by Professor Mindlin's method are higher than those in actual soil. In the future it may be possible to take these two factors into consideration by introducing the cohesion coefficient and the internal friction angle of the soil.

This will be a difficult task, however. With the foregoing explanation in mind, the coefficient R_c in the paper should actually be called R_m to differentiate it from the actual R_c, which is the ratio of the load delivered per linear foot of pile at the top of the pile to the load delivered per linear foot at the bottom of the pile. When this has been done, vertical shears at midheight of friction piles (corresponding to an average of vertical shears for the full length of piles) and safe loads may be computed in practice as indicated in the paper.

Approximate Formula for Vertical Shear in a Pile Group.—Table 6 for the determination of the interaction of piles in a group can also be used by considering the vertical shears as inversely proportional to the center-to-center distances between the piles, in which case the error would not exceed 3%. In the case of pile A—

$$s_{vA} = \frac{P}{2\,\pi\,r_1\,L} \quad \text{(17)}$$

equals 0.005780 at the midheight of the pile. An even better approximation can be obtained by assuming that the influence of a distant pile A_n on pile A_1 is inversely proportional to $\frac{r_{1n}\,(L^2 + 4\,r^2_{1n})^{1.5}}{r_1\,(L^2 + 4\,r^2_1)^{1.5}}$, in which r_{1n} equals the distance, $A_1\,A_n$, r_1 = radius of pile A_1 at midheight. This value is then multiplied by the sine of the angle of the line of action. The foregoing proportion is obtained from Eq. 2*c* by neglecting the term with the coefficient $R_c - 1$, and letting Z equal $\frac{L}{2}$; then,

$$s_v = \frac{P\,L^2}{2\,\pi\,r\,(L^2 + 4\,r^2)^{1.5}} \quad \text{(18)}$$

In Eq. 18, R_c from the first part of Eq. 2*c* disappears, as was to be expected for Z equals $\frac{L}{2}$ with a linear load distribution. By using Eq. 18 instead of Eq. 2*c* the error is less than 1%, and for the practicing engineer it is more convenient. The vertical pressure beneath the group of piles can be computed as indicated in the paper. In this case again, Eq. 4*b* can be simplified for the plane through the tip of the pile, as follows:

$$\phi_v = \frac{2\,P}{\pi\,L\,r\,(R_m + 1)} \quad \text{(19)}$$

This gives a very good approximation (R_m from Eq. 19 has the same value as R_c from Eq. 4*b*.

In conclusion, it may be stated that by using a coefficient R_m, a better approximation of the stress distribution around the pile corresponding to the true distribution in the soil can be obtained. A better insight into the true behavior of soil under the forces exerted by a friction pile can be obtained only by actual tests. The theoretical approach of the load distribution for a friction pile, as developed in this discussion, was completed by the writer during the aforementioned tests of Grande Couronne in 1935. Then it was found that only through the elastic behavior of the pile, and by the measurements of displacements of different points alongside the pile, could the real distribution of the load be obtained, and some other problems of the soil mechanics approached.

A. E. CUMMINGS,[15] M. AM. SOC. C. E.—The question of the relative carrying capacities of single piles and pile groups has been a controversial subject among foundation engineers for many years. The experiments described in this paper might have served to add materially to the available knowledge on this problem. Unfortunately, it appears as though too much effort was devoted to the development of an unsound mathematical theory and too little effort to the development of a carefully thought out test program that would include field measurements of all of the quantities that are important in problems of this kind.

Referring to the mathematical theory, the author's effort to use the Boussinesq point-load equations simply adds another chapter to the long story of the incorrect application of these equations to all kinds of foundation problems. Several years ago, the writer published[16] the original derivation of the Boussinesq equations together with a statement of the fundamental assumptions on which the derivation is based. Whenever these equations are applied to an actual problem, it is necessary to keep these basic assumptions in mind and to make sure that the conditions of the problem do not conflict with the assumptions under which the equations were derived.

For example, one of Boussinesq's fundamental assumptions is that the load is applied at the plane boundary of the semi-infinite, elastic, isotropic, solid and not at some point below the surface of the solid. The author has used the Boussinesq equations for loads that are applied below the surface of the ground although it has already been explained by Raymond D. Mindlin,[17] Assoc. M. Am. Soc. C. E., why the Boussinesq equations cannot be used in this manner to determine the distribution of stresses around a pile. Furthermore, the author does not appear to have given any consideration to some of the other fundamental assumptions of the mathematical theory of elasticity on which the Boussinesq equations are based. In particular, the paper says nothing about strains or displacements, although these are just as important as the stresses in problems of this kind. Also, the author's extension of his analysis from the single pile to the pile group presupposes the validity of the principle of superposition. It is of considerable interest to examine the author's proposed theoretical solution from the standpoint of displacements and the principle of superposition.

As is well known, the entire mathematical theory of elasticity is based on Hooke's law concerning the proportionality of stress and strain. Whenever a force is applied to an elastic body, some kind of displacement occurs as a result of that force. The problem under consideration is no exception to this rule and the stresses determined by the author would necessarily be accompanied by displacements in the soil surrounding the pile. Since the author has assumed the soil to be incompressible (Poisson's ratio = 0.5), the horizontal tangential stress vanishes everywhere and the two normal stresses given by Eqs. 1*a* and 1*b* will determine the horizontal radial displacements by means of the equation

[17] "On the Distribution of Stress Around a Pile," by R. D. Mindlin, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Cambridge, Mass., Vol. III, 1936, p. 71.

$$u = -\frac{r}{2E}(q_v + q_h) \qquad \text{.......................(20)}$$

in which u is the radial displacement, and E is Young's modulus of the soil. The vertical displacements, w, may be obtained in a similar manner from the author's stress equations.

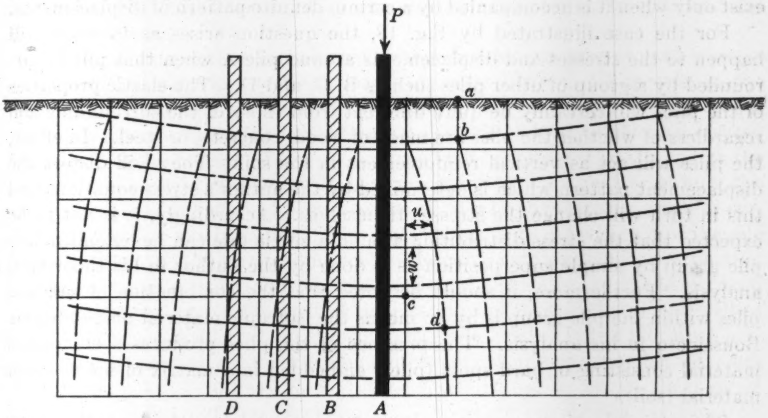

Fig. 18

Fig. 18 represents any meridional plane in the soil through the vertical axis of the pile A. The solid lines represent an imaginary rectangular network existing in the ground after the pile is driven and before any load is applied to the pile head. When the load, P, is placed on pile A, stresses are set up in the soil around the pile, and these stresses are accompanied necessarily by certain vertical and radial displacements in the soil. The dotted lines in Fig. 18 are a qualitative representation of the distortions that would occur in the rectangular network due to the displacements determined by the author's theoretical stresses. The actual amounts of the displacements would depend on the magnitude of the load, P, and on the numerical value of Young's modulus, E, of the soil. All points on the ground surface would be displaced vertically downward and there would be no radial displacements at the ground surface because of the assumption of incompressibility (Poisson's ratio = 0.5). For example, a soil particle originally at a would move to b. Within the soil, all vertical cylindrical surfaces concentric with the vertical axis of the pile would be bulged radially outward and all horizontal planes would be bent downward. A soil particle originally at point c would move to point d.

This system of displacements is a necessary consequence of the author's stress system. If the stresses in the soil were those determined by the author, the displacements would have to be of the type shown in Fig. 18. It is conceivable that such a system of stresses and displacements could exist in the soil in the vicinity of a single pile. However, if the soil around the pile were subjected to restraints that would affect the displacement pattern, these restraints would also affect the stress pattern. This follows inevitably from the fact that the entire mathematical theory of elasticity is based on a definite set of stress-strain relationships. Boussinesq's stress equations were derived with the aid of the basic differential equations which relate the stresses to the space derivatives of the displacements. Accordingly, the Boussinesq stress pattern can exist only when it is accompanied by a certain definite pattern of displacements.

For the case illustrated by Fig. 18, the question arises as to what will happen to the stresses and displacements around pile A when that pile is surrounded by a group of other piles such as B, C, and D. The elastic properties of the piles will certainly be quite different from those of the surrounding soil regardless of whether the piles are made of wood, concrete, or steel. In effect, the piles will act as vertical reinforcement in the soil. They will distort the displacement pattern which is determined by the author's stress equations and this in turn will change the stresses themselves. Accordingly, it is not to be expected that the stress distribution around a single pile can be extended to a pile group by simple superposition as is done by the author in his theoretical analysis. Furthermore, it should be noted that the combination of soil and piles within the pile group is by no means the isotropic material postulated by Boussinesq in his analysis. The presence of the piles produces a compound material consisting of hard spots (piles) embedded in a matrix of much softer material (soil).

The principle of superposition is sometimes used to determine the stress distribution in foundation problems. For example, a large mat foundation is often divided into small segments and the stress distribution for each segment is computed as if the segment were a point load.[18] The stresses produced by each segment are then added by simple superposition to obtain the stress distribution for the entire mat. This application of the principle of superposition to a mat foundation is something quite different from the application of that principle to a pile group. In the case of the pile group, each additional pile affects the elastic properties of the underground. Even though the soil around a single pile might be considered as having the properties of an elastic isotropic material, the introduction of additional piles destroys the isotropic properties and materially changes the elastic properties. Accordingly, the author's method of applying the principle of superposition to a pile group is an incorrect procedure.

Another factor in this problem to which the author has paid no attention is the contraction of the pile itself. After the pile is in place in the ground and before any load has been applied to the pile head, there is no shearing stress in the soil such as that given by Eq. 2*c*. When a load is applied to the pile head, there is a downward movement of the upper end of the pile due to the elastic shortening of the pile. As the pile starts to move with respect to the surrounding soil, the movement mobilizes the shearing resistance of the soil. Since the movement begins at the top of the pile, the mobilization of shearing resistance in the soil also begins at the top of the pile near the ground surface. When a small load is applied to a long friction pile, all of the reaction for the load is developed in the soil around the upper part of the pile. The load produces no stress in the lower part of the pile and consequently no elastic contraction and no mobilization of shearing resistance in the soil surrounding the lower part of the pile. As the load is increased the stress in the pile approaches the pile point but it does not actually reach the point until the load attains a certain value which is determined by the elastic properties of the pile and the surrounding soil.

---

[18] *Proceedings*, Am. Soc. C. E., May, 1933, p. 784.

In Fig. 6, the author has computed the shearing stresses around a single pile 60 ft long carrying a 10-ton load. A value of $R_c = 1.5$ is used in the calculation. Actually the value of R_c would be very much greater than 1.5 for the conditions shown in the figure because little or no load would be delivered to the soil at the bottom of the pile. If no load is delivered to the soil at the bottom of the pile, the value of R_c becomes infinite. As a matter of fact, the determination of the numerical value of R_c should be the starting point for any theory of friction pile behavior. The real problem is to determine how the pile delivers its load to the surrounding soil. The author states that R_c is a function of pile length, pile taper, and internal friction of the soil. He has overlooked the fact that it is also a function of the elastic properties of the pile as well as a function of the load that is applied to the pile head. If the pile were perfectly rigid so that no elastic shortening of the pile would occur under any load, it might be possible to have $R_c = 1.5$ for all loads and to have a shear-stress distribution similar to that shown around the single pile in Fig. 6. Since all actual piles are elastic and will therefore shorten under compressive stresses, this elastic shortening will influence the transfer of load from the pile to the soil. The value of R_c, therefore, will depend on the elastic properties of the pile and on the amount of the applied load as well as on the three factors mentioned by the author.

The usual procedure in the case of a pile load test is to place the load on top of the pile and then to measure the downward movement of the head of the pile for each load increment. It is not possible to determine the elastic shortening of the pile from such measurements because nothing is known about the movement of the pile point. Neither can such measurements furnish any information as to the manner in which the pile transfers the load to the surrounding soil. On the other hand, if the actual elastic shortening of the pile were determined by suitable measurements, it would be possible to determine from these measurements approximately how the pile was transferring its load to the soil. For example, it is a simple matter to compute what the elastic shortening of the pile would be if it were a free-standing strut with no part of the load supported by friction on the sides of the strut. When any part of the load is supported by friction along the sides of the pile, the elastic shortening is always less than it would be for the same pile carrying the same load as a free-standing strut. When all of the load is carried by side friction as in the author's problem, it is possible to compute the elastic shortening of the pile for any assumed distribution of friction along the sides of the pile. This can be done even if the friction distribution is assumed to be discontinuous due to soil stratification.

Conversely, if the elastic shortening of the pile is carefully measured in the field, it is possible to deduce the friction distribution from the field measurements.

Experiments of this kind have been made in The Netherlands by C. Franx,[19] G. C. Boonstra,[20] and others. The piles tested in The Netherlands were precast concrete piles. When they were cast, a piece of 1.5-in. pipe extending the full length of the pile was placed in the vertical axis. A 1-in. rod was inserted in this pipe and fastened at the pile point. The test load was applied to the driven pile in such a manner that it was possible to measure the deflection of the pile head and also the movements of the 1-in. rod which gave the deflections of the pile point. The difference between the two readings for any given load represented the elastic shortening of the pile at that load. In Fig. 19, curves a and b are reproductions of a pair of load-settlement curves measured by Boonstra. The solid line shows the settlement of the pile head and the broken line that of the pile point. The specimen was a reinforced pre-cast concrete pile of octagonal cross section, 16 in. in diameter and 70 ft long. It was driven through 50 ft of soft clay and peat, 15 ft of fine sand, and then into sand and gravel for a depth of about 6 ft. The condition was similar to that of pile T20 of the author's tests.

As can be seen from Fig. 19, there was practically no movement of the pile point until the load amounted to 15 or 20 tons although the head of the pile began to move as soon as the loading was started. The vertical distances between the two curves, a and b, represent the elastic shortening of the pile, but in order to show this relationship more clearly, curve c, Fig. 19, was plotted with loads as abscissas and elastic shortening as ordinates. It is easily seen from this figure that the relationship between load and elastic shortening is not linear. If the distribution of load transfer from pile to soil were constant throughout the entire load range (R_c = constant), and if the pile material were perfectly elastic, curve c, Fig. 19, would be a straight line. As to the elastic properties of the pile, it could be expected to behave under load like a reinforced concrete column. The stress-strain curve for such a column might be slightly curved but the curve would be concave toward the strain axis, whereas most of curve c, Fig. 19, is concave toward the stress axis. Accordingly, the only conclusion that can be drawn from curve c is that the distribution of load transfer from pile to soil varies throughout the load range. In other words, R_c is not a constant. As the load is increased, the transfer of load from pile to soil distributes itself in various ways depending on the elastic properties of the pile and the soil and on the amount of the load. The sudden break in curve c at about 150 tons indicates that the upper part of the pile probably broke loose from the surrounding soil entirely so that practically all of the applied load was resisted by the lower end of the pile which was in the sand and gravel.

Consideration of this type of test data raises a serious question as to the validity of the figures presented in Table 8. All of the pile loads given in this table are computed with $R_c = 1.5$ on the assumption that the distribution of load transfer from pile to soil is constant over a wide range of loads and pile lengths. The author's computation implies that R_c is an independent variable to which numerical values can be assigned for the purpose of computing pile loads. Actually, the situation is just the reverse. The amount of the load influences the manner in which the pile transfers load to the soil so that the numerical value of R_c depends on the load.

[19] "Proefbelasting van Heipalen te Rotterdam," by C. Franx, *Polytechnisch Weekblad*, 1934, Nos. 23, 24, and 25.

[20] "Eenige Beschouwingen over den Puntweerstand van Palen," by G. C. Boonstra, *De Ingenieur*, February 23, 1940, Vol. 55, No. 8, p. B-33.

This aspect of the problem is something that could easily have been investigated in the Morganza tests. It would have been possible to set three or four rods in a hollow concrete pile, such as pile C9, so that settlement observations could have been recorded not only at the pile head but also at the pile point and at several places along the length of the pile. If the strains in the pile itself had been measured, it would be possible to determine how the pile was transferring load to the soil at each load increment.

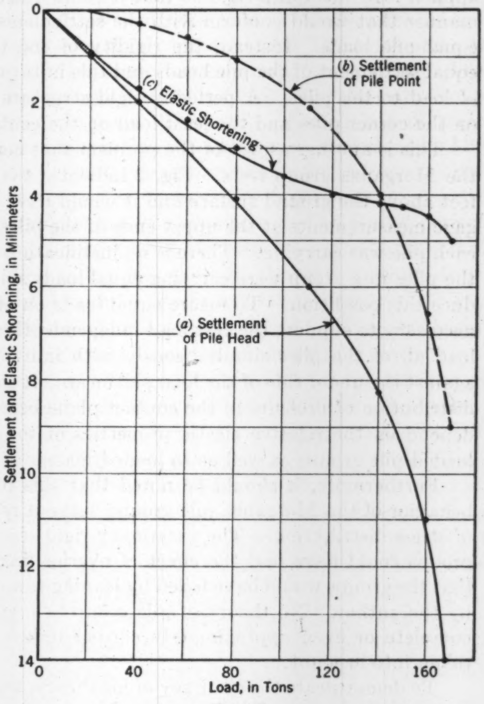

FIG. 19

Because he has completely neglected the entire question of strains and displacements, the author has developed a mathematical analysis that is theoretically unsound and of no practical value. The analysis is based on the mathematical theory of elasticity but nowhere in the paper is there any mention of the elastic properties of the piles themselves. The author has treated the piles as though they did not exist except as imaginary vertical line loads in the soil. Unfortunately, this method has led to a theoretical stress distribution which, in the writer's opinion, must also be classified as imaginary. The piles are actual physical bodies having certain elastic properties, and neither the single pile nor the pile group can be analyzed without taking these elastic properties into account.

Throughout his theoretical analysis of pile groups the author has assumed that each pile in the group would be subjected to the same load as all of the others. He has made this same assumption in connection with the groups that were actually tested. This question of load distribution over the pile heads is an important factor in pile group behavior. The author has referred to this subject in his conclusions by remarking that the piles under the outer edges of a stiff pier base would be subjected to greater loads than those under the center. This remark is perfectly true but the question arises as to what was happening in this respect during the Morganza group tests.

Fig. 2(*c*) shows the load arrangement that was used for the 16-pile group. If each pile in the group were subjected to the same load, the center piles could be expected to settle the most, the edge piles would settle somewhat less, and the corner piles would settle least of all. The photograph indicates that the applied load was quite rigid so that it could scarcely be expected to warp in a manner that would conform with the settlements that would be produced by equal pile loads. Instead, the rigidity of the test apparatus would require equal settlement of the pile heads and this in turn would affect the distribution of load to the piles. A perfectly rigid structure would put the greatest load on the corner piles and the least load on the center piles.

This is another aspect of the problem that could have been investigated in the Morganza group tests. Fig. 2 indicates that the pile heads were several feet above the ground surface and it would have been possible to make strain-gage measurements at the upper ends of the piles to determine how much load each pile was carrying. There is no justification for the assumption that all of the piles in a group were carrying equal loads since no effort was made to produce this condition. To insure equal loads on all piles in a group it would be necessary to support the test load independently of the pile group and then to load all of the piles simultaneously with individual hydraulic jacks reacting against the under side of the load platform. It should be kept in mind that the distribution of pressure in the contact plane between any two solid bodies will depend on the relative elastic properties of the two bodies. This applies to loaded pile groups as well as to loaded masses of earth or other materials.

Furthermore, it should be noted that this phenomenon could explain the behavior of the Morganza pile groups without reference to the author's theory of stress distribution. The practically rigid structures built on top of the pile groups could have had the effect of overloading the corner and edge piles so that the groups would have failed by leaning toward a corner or side as described by the author. No theory of pile group behavior can be considered as being complete or even approximately correct unless this phase of the problem is taken into account.

To demonstrate the accuracy of his theory, the author has prepared Table 5, which indicates a remarkably close agreement between theoretical and actual failure loads. However, the writer finds it difficult to follow the line of reasoning used by the author in his selection of shear values on which the comparisons are based. An average value is used for four of the group tests, and the other three are compared with values determined for certain individual piles. Referring to Fig. 1, these two profiles represent cross sections of the floodway 4 or 5 miles wide. The profiles themselves are some miles apart along the length of the floodway. The single piles, as well as the pile groups, are therefore scattered over distances that are measured in miles, and the first question to be decided is whether the comparisons should be based on averages or whether each group test should be compared with the results of the nearest single pile.

It is of considerable interest to examine Table 5 with these ideas in mind. To check the T2–T9 group, the author used pile T1 which was 130 ft from the group. However, pile T10 was only 294 ft from the group. Accordingly, if the proper way to handle this problem is by means of averages, it would seem reasonable to average T1 and T10 in order to check this group. Such a procedure would not check the theory so closely because the average friction developed by T1 and T10 was 792 lb per sq ft, whereas the author used 685 lb per sq ft from T1 alone. On the other hand, if the proper way to handle this problem is by comparing each group with the nearest single pile, groups T11–T19, T21–T29 and T37–T52 should be compared with T20 alone and not with an average that includes piles that are miles away from these groups. The distance from group T11–T19 to group T21–T29 is 1,958 ft and the third group as well as pile T20 are between the two. However, a comparison of these groups with pile T20 would not check the theory so well because pile T20 developed a friction value of only 680 lb per sq ft, whereas the author checked these groups by using the general average value of 778 lb per sq ft.

The data given in Table 5 indicate that the tests provided an almost perfect check of the author's theory. The agreement between theoretical and actual loads is really too perfect in view of the fact that the theory is unsound from the point of view of both mathematics and theoretical mechanics. In the writer's opinion, the author's theory is analogous to the old Ptolemaic theory of a geocentric solar system. For 1,400 years the Ptolemaic system was accepted generally because it appeared to be able to account for the motions of the planets. After Galileo invented the astronomical telescope, astronomers were able to stop speculating and start measuring. The very first measurements caused the abandonment of Ptolemy's geocentric system in favor of the modern heliocentric system. The fact that Galileo got into trouble for measuring things and upsetting an ancient theory should not discourage modern engineers from making all the measurements that can possibly be made in a given experiment. A theory based on insufficient data can appear to be practically perfect and yet be completely wrong.

The writer joins the author in the hope that engineers interested in pile foundations will continue to make tests to determine how such foundations behave under load. However, the writer considers it necessary to supplement that hope with several suggestions. To develop an adequate theory for the behavior of a single friction pile, it will be necessary to determine, by means of suitable field measurements, how the pile transfers its load to the surrounding soil. In order to develop an adequate theory for the behavior of a group of friction piles, field measurements must be made to determine the distribution of load to the pile heads in addition to the measurements that are required to determine the distribution of load transfer from pile to soil. Field measurements that include only a record of the settlement and rebound of the pile head are inadequate for the development of a theory of friction pile behavior.

Frank M. Masters,[21] **M. Am. Soc. C. E.**—It was the author's idea to present, in this paper, test data which seemed to demonstrate some facts about group action in timber friction piles that previously had been largely a matter of conjecture. The tentative theory for the calculation of failure loads of groups proposed in the paper appeared to check the test results and therefore seemed to have some merit. Such a theory can be of value only if it meets all conditions and if it is improved by criticism. The writer, therefore, sincerely appreciates the resulting comment and criticism.

Mr. Connor offers a number of practical suggestions on pile spacing that are too often neglected by the designer. He also gives data on heavy loads actually carried by friction piles driven into soft material which, during driving, did not appear to be able to support such loads. Mr. Connor further presents an interesting method of comparing the strengths of different groups of piles on the basis of comparative perimeter areas of soil around the groups. This method evidently gives a close approximation as between groups; but it is not possible to use this method to compare single piles with groups.

Mr. Woodruff raises several points of interest. The writer agrees that all predictions of pile strength using this theory will not have the accuracy of agreement between theory and tests apparently indicated in Table 5; nor does it seem that such accuracy is altogether necessary in the design of pile foundations. Further, it is quite possible, as Mr. Woodruff suggests, that soil consolidation around the piles over a long period of time may affect their settlement somewhat; but it does not seem likely that such a long-time consolidation should affect the shear strength of the soil adversely and lead to pile failure. It is anticipated that settlement readings will be made on the Morganza Floodway structures over a period of time. It is to be noted in connection with long-time loadings that one of the pile groups on the N. O. T. & M. Crossing, group T21–T29, was loaded over a period of 243 days with a constant load of 20.3 tons per pile without apparent additional settlement after the first day.

Mr. Feld suggests that a tapered timber pile actually may carry with it, in failing, a complete cylinder of soil having a diameter equal to the butt diameter of the timber pile. He points out that under this assumption the shearing value of the soil at failure would be 600 lb per sq ft and would be more nearly in correspondence with the value of 558 lb per sq ft indicated in Table 4 for parallel-sided concrete piles. He also describes an approximate rule for determining group strengths by subtracting progressive one sixteenths from the value of all piles after the first, as every new pile is added to the group. This apparently gives satisfactory results for the examples cited, but does not take account of pile spacing in relation to length or diameter, which the writer believes has an important bearing on the strength of piles in a group.

Mr. Greulich states that the law of averages probably contributed to the agreement between theory and tests as recorded in Table 5, and with this the writer agrees. Mr. Greulich cites an interesting example of group action in piles under the large foundations of pivot piers of swing bridges, where an earlier designer found he must restrict working loads to as low as 7½ to 8 tons per pile.

---

[21] Cons. Engr. (Modjeski & Masters), Harrisburg, Pa.

Mr. Paxson gives a graphic comparison of pressures beneath pile foundations as compared with pressures beneath spread foundations, showing the considerably greater pressure under the spread foundation, and giving emphasis as well to the fact that this greater pressure is at a point near the surface where soil conditions are generally poorer than near the elevation of pile tips.

Professor Mindlin states that a solution of the equations of elasticity, known as the Boussinesq solution, was used in the writer's paper, and that the integrated Boussinesq formula is not applicable to pile foundations. It is not to be inferred that, because the writer used the Boussinesq solution, he accepts the concept of elasticity in soils. The Boussinesq solution was used because it appeared to fit satisfactorily the results of tests to failure better than did any other formula. Nowhere in the writer's paper was there any mention of the word "elasticity"; this was a deliberate omission because it is not believed that soils are perfectly elastic. This is especially true in connection with the tests given in the paper which were carried to failure, well beyond any possible range of elasticity in the soil.

Professor Mindlin states that it is not possible to compute a curve of Mindlin distribution for a uniform load per linear foot from the data given in Table 10. The method used in the preparation of Fig. 11 was as follows: Part (*a*) of Table 10 gives the pressures at various radii from the pile for various depths. These data permit a computation of the total vertical force on a circle of 0.1 radius, 0.2 radius, 0.3 radius, 0.5 radius, etc., at such depths. For a pile transmitting a uniform load per linear foot to the soil, the total load distributed from the top to 0.25 L depth is $\frac{1}{4}P$, and to 0.50 L depth is $\frac{1}{2}P$. If, from these distributed loads, there are subtracted the total vertical forces acting on the circles of various radii already cited, the difference in each case is the total shear carried by the cylindrical surface of the cylinder of earth from the top of pile to the depth 0.25 L or 0.50 L. For each radius a curve of total shear may be drawn, starting from 0 at the top to a calculated value at 0.25 L, to a larger calculated value at 0.50 L. The slope of this curve at any point is the shear transmitted by a circumferential band one unit high. If this slope is divided by $2\pi r$, it will give the shearing intensity per square unit. The curve of Mindlin distribution in Fig. 11 was based on the slope of the various curves at midheight of the pile. Any error that exists as a result of the graphical method used is believed to be slight.

Professor Mindlin questions the principle of superposition applied to pile groups. Of course, there are many unusual stresses created between piles in a group due both to the existence of the other piles and to soil stresses created during driving. Nevertheless, there seems to be no reasonable way of determining the build-up of stresses under pile loads unless loads from various piles are superimposed upon one another.

Professor Mindlin states that the real problem is to determine the distribution along the pile of the load transfer from pile to soil. There are certain practical ways of arriving at this solution. When a timber pile is started in the ground and the hammer is placed upon it, it will often settle into the soil a distance of several feet. In the case of the Morganza piles, this distance of embedment into the soil under the weight of the hammer used was such as to suggest that the shearing strength of the soil near the surface was reasonably close to the average shearing strength at failure of the pile. As was emphasized in the paper, when some allowance is made for the comparatively larger diameter of the butt as compared with the tip of a pile, and when there is reason for the belief that the shearing strength of soil increases slightly with depth, it is reasonable to arrive at such a value of R_c as was used in the paper. Incidentally, such practical data as these, secured during driving operations, may often give a clue as to the variations in material from ground to tip of pile. In a recent study undertaken in the writer's office, dealing with a pile foundation at another locality, it was discovered that this sinking of the pile under the weight of a 9,700-lb hammer amounted to 15 ft, indicating a shearing strength of soil at the surface of the ground of only 400 lb per sq ft, whereas the entire pile failed under an average skin friction of 975 lb per sq ft. This indicated a considerable variation in strength of material and suggested a method of arriving at a value of R_c for the pile group in question.

Mr. Solomon demonstrates mathematically the effect of the elasticity of the pile upon R_c and proves that for small pile loads the pile tip actually may deliver no load to the soil. Since the shearing stresses computed in the paper were primarily related to failure loads on the piles, the value of R_c used must be considered as applying particularly to such failure loads. Mr. Solomon also suggests that some of the difference in skin friction value between concrete and timber piles may be due to the effect of weight of the concrete piles as compared with the weight of timber piles. All of the larger concrete piles were hollow and had a weight no greater than the weight of the earth which they displaced. If a cylinder of earth is visualized as standing in soil, there will be no vertical shear along its vertical surfaces except that created by an applied load on top of the cylinder. For that reason, the weights of the piles themselves were uniformly and properly neglected in computing skin frictions under loads.

Mr. Cummings declares that the Boussinesq solution is not applicable to piles in an elastic soil, and shows that a combination of piles and soil is not isotropic. He restates the effect of contraction of the pile upon the distribution of load to the soil, and questions the equality of loads on the various piles of a group in the Morganza tests. Mr. Cummings evidently feels that not enough measurements were made and that the Morganza tests were not up to the experimental standard established by Galileo. In that connection, although the writer has heard many suppositions as to the effect of grouping upon pile strength, he knows of no previous tests of the scope of the Morganza tests to establish by measurement what this grouping effect is at failure. The writer also wishes to restate a fact which appeared in the paper—that these tests were originally intended to satisfy the requirements of current specifications, and that certain failures of small groups suggested that the tests be extended to larger groups. The writer is indebted to the Corps of Engineers, U. S. Army, for their cooperation in making possible these supplementary failure tests on large groups. The theory was then developed, using that method of distribution which would check the tests to failure and, by such a practical check, the method served to cancel the numerous variables which are cited by Mr. Cummings.

Mr. Cummings also objects to the use of average value of shear strength over the several crossings in cases where single pile tests were not close at hand. This was done because it seemed the most reasonable approach, since funds had not been available to make a single pile test close to each group test. However, after the paper was published, the N. O. T. & M. Railway, at its own expense, made a failure test on a single 50-ft pile immediately adjacent to the 16-pile group, T37–T52, and obtained a failure shear value of 735 lb per sq ft at this location. The 16-pile group used 60-ft piles, which might be expected, due to their increased depth, to develop somewhere between this value of 735 and the average value of 778 lb per sq ft used in the study.

In conclusion, the writer hopes that opportunity may arise to study the effect of grouping by all of the methods proposed, both in the discussions and in the paper, and urges that every effort should be made to relate all theories developed to actual load tests in the field.

Paper No. 2175

ALLOCATION OF THE TENNESSEE VALLEY AUTHORITY PROJECTS

By Theodore B. Parker,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Malcolm Elliott, E. L. Chandler, Eugene L. Grant, Sherman M. Woodward, Albert R. Arledge, C. W. Watchorn and F. A. Allner, and Theodore B. Parker.

Synopsis

The various theories applicable to the allocation of costs of a multiple-purpose water control project, and the procedure followed by the Tennessee Valley Authority in allocating the cost of its first three dams to navigation, flood control, and power, are presented in this paper. It is shown that a large difference in the allocation of the common costs of a project affects to a much lesser degree the proportions of the total cost charged to the individual purposes. Consequently, the final allocations are approximately correct, within reasonable limits, regardless of the exact method adopted.

Requirements of the Act

The allocation problem of the Tennessee Valley Authority (TVA) was necessitated by Sections 9*a* and 14 (see Reference 1 in the Appendix) of the Tennessee Valley Authority Act as amended. It is to be noted at the outset that Section 9*a* specifically provides for the generation of power only in so far as it is consistent with the primary purposes of navigation and flood control and that the proceeds of the sale of power are "to assist in liquidating the cost or aid in the maintenance of the projects of the Authority."

The location and the minimum pool elevations of the Authority's dams on the main Tennessee River (Fig. 1) were determined by navigation requirements, whereas the surcharge pool elevations were determined by the maximum amount of flood control storage space consistent with a minimum damage to the cities and agricultural areas. Dams on the tributary rivers were chosen principally with regard to flood control purposes. All of these dams operating together as a unified power system, in so far as possible after satisfying the primary purposes of navigation and flood control, produce a large amount of power.

Note.—Published in December, 1941, *Proceedings*.

Nevertheless, the intent of the Act is clear and is rigidly followed in actual practice and in the operation of the Authority's system.

With regard to the allocation problem, two reasonable points of view could be taken. The power generated by the different dams could be considered only as by-product power. In Section 14 (see Reference 1 in the Appendix) the Act declares

> "* * * as soon as practicable to make the power projects self-supporting and self-liquidating the surplus power shall be sold at rates which in the opinion of the board, when applied to the normal capacity of the Authority's power facilities, will produce gross revenues in excess of the cost of production of said power."

This might be taken to mean that the rates should be such that they will pay only for all additional facilities especially necessary to install power equipment at the Authority's dams together with all transmission facilities without, however, paying any share of the dams themselves. A second interpretation would include in the cost of production a share of the cost of the facilities used jointly with navigation and flood control.

In July, 1940, Congress appropriated funds for the construction of the Cherokee hydroelectric project, the Watts Bar Steam Plant, and the installation of additional units at existing downstream plants. In July, 1941, four additional hydroelectric projects on the Hiwassee tributary and additional units in downstream plants were authorized. At present (October 20, 1941) Congress is considering the authorization of two additional tributary projects. These projects will be operated primarily for power production during the present national emergency, after which all of the projects will be operated on a multiple-purpose basis, and their total cost will be allocated to navigation, flood control, and power.

History of Procedure

In order to assist in the task of determining the proper theory and to make the necessary studies, the TVA Board of Directors created a Committee on Financial Policy consisting of the comptroller as chairman, the chief engineer, the chief water control planning engineer, the solicitor, the chief power planning engineer, and the chief budget officer. It was the opinion of this committee, acting with the advice of a number of consultants, that in order properly to assist "in liquidating the cost or aid in the maintenance of the projects of the Authority," a part of the joint costs should be allocated to power. In other words, although the committee recognized the limitation of the power program by priority given to navigation and flood control requirements in the planning and operation of the projects, the economies of the multiple-purpose developments are shared by all purposes.

In allocating a part of the joint costs to power the program was thereby placed on practically the same basis as (for instance) a private company that builds its own power facilities at an existing government navigation dam and pays the government a fee for the use of the head created by the dam. This fee may be considered to repay the government for a part of the cost of constructing the dam (see References 2 and 3). Still another comparison might be made with a private company building a dam and power development on a navigable stream, the government building a navigation lock at the same location and granting the company a reduction or waiver of the license fee which would normally be required.

Such agreements between the U. S. Government and private companies are in effect examples of cost allocations, similar in character to the cost allocations at TVA dams.

At all times, the TVA Board of Directors was kept informed of the committee's work, and after the first "Report of the Investment in the Wheeler, Norris and Wilson Projects and the Allocation of the Investment Among the Several Purposes of the Tennessee Valley Authority Act," the committee submitted to the Board each year a report on the allocation of the Authority's investment in the system completed during the previous fiscal year. The first report, which was published as House Document No. 709, 75th Congress, 3d Session, included a full description of the committee's considerations leading to the allocation of the Authority's investment in the multiple-purpose projects to the various purposes.

THEORIES OF JOINT-COST ALLOCATIONS

The various theories of joint-cost allocations described in House Document No. 709 are summarized herein. It should be observed that allocations of costs are concerned principally with the proper apportionment of the cost of the structures and facilities which are used jointly for the various purposes of the development. Expenditures made solely for any single purpose are to be charged directly to that purpose. The following methods of allocation were considered by the committee.

Vendibility Theory.—Under competitive open market conditions, products jointly produced will generally be sold at prices totaling the joint cost of production plus a reasonable profit. Apportionment of costs will depend largely upon the demand for the products separately. This theory breaks down because there is no open market in which the services produced by the Authority under conditions of joint supply càn be sold. Navigation and flood control, under present conditions, are not vendible commodities.

Benefit Theory.—This theory advocates apportionment of joint costs on the basis of estimated benefits derived from the completed development.

The difficulties peculiar to this theory are principally those of evaluation of the benefits. Beneficial effects of any one project are multitudinous. Some of these are gains to individual property owners, reduction in costs to consumers, profits to merchants and industrialists, advantages of a social and governmental character; some are specific, others general in nature; some are easily evaluated, others are intangible; some are local, others remote from the Valley; some are immediately effective, others will benefit future generations. House Document No. 709 presents this theory in some detail and furnishes much pertinent information.

It is necessary to distinguish between two versions of the benefit theory. According to one version, the benefits would include the over-all advantage to the entire country from the projects constructed by the Authority. According to the other version, the benefits would be measured by the alternative cost of obtaining equivalent results by single-use projects, provided the advantages to the country can be shown to be sufficient to justify the expenditure necessary to construct such a single-use project. This second interpretation is probably the most workable of any of the methods that have been considered and is discussed in House Document No. 709 under the name of "alternative-justifiable-expenditure theory." A similar method was suggested for allocating joint costs between navigation and power for the St. Lawrence River project on the international section of that stream, and has also been used as a basis for allocating joint costs of water utilities between commercial service and fire-protection service.

Use of Facilities Theory.—This theory would distribute joint costs upon the basis of comparative use of the joint facilities. To each single function would be allocated such share of the joint cost as is measured by the extent of its use.

In the steam railroad field, for example, the apportionment of common cost between freight, mail, express, and passenger business may be made upon some comparable use units like car-mile, passenger-mile, or ton-mile measure.

When applied to the TVA problem, the theory becomes very involved; an acre-foot of reservoir capacity or an acre-foot of water released has been suggested as the common unit; but when considering power, head is an essential feature, whereas for flood control, head is not an essential factor. It is possible, however, that the theory might be usable after sufficient records have been collected over a considerable period of time regarding the actual use which has been made of the facilities. For the immediate future, the theory appears not to be workable.

Equal Apportionment.—This may be considered as a common-sense rule of equity to be used when it is felt that no truly scientific basis of apportionment can be found. However, such a rule does not seem practicable where the respective uses for each function are not equal.

Special Costs.—This theory suggests the apportionment of the costs to the several uses in direct proportion to the special expenditures made for each use. The procedure appears irrelevant where the object of the allocation is to impute responsibility for joint costs.

Alternative Justifiable Expenditure.—This theory proposes to divide the joint costs in proportion to the alternative justifiable expenditure less the direct cost for each function. By constructing projects which serve multiple uses, savings may be achieved in expenditures over those necessary for single-use projects.

According to the theory (see Reference 4 in the Appendix), the direct cost for any one purpose corresponds to the investment that could have been eliminated from the total project cost if that purpose had not been included in the development of the project. The alternative justifiable expenditure for any one purpose is the lowest cost of realizing an equal benefit to that obtained in the multiple-use project by a development undertaken solely for that purpose provided such expenditure is justified by the benefits obtainable.

Table 1 illustrates the application of this theory to the following simple hypothetical case—the assumed allocation of $1,000,000:

Assumed Direct Costs:		
Navigation	$ 150,000	
Flood control	100,000	
Power	250,000	
Total		$ 500,000
Common costs		500,000
Total project cost		$1,000,000
Assumed Alternative Costs:		
Navigation	$ 400,000	
Flood control	300,000	
Power	600,000	
Total	$1,300,000	

A conclusion as to the various allocation theories considered is given in the Appendix (see Reference 5).

TABLE 1.—ASSUMED ALLOCATION OF $1,000,000

Facility (1)	Alternative costs (2)	Direct costs (3)	Remaining costs; Col. 2 minus Col. 3 (4)	Percentage of total (5)	Allocation of common costs (6)	Direct costs added; Col. 3 plus Col. 6 (7)	Percentage of total (8)
Navigation	$400,000	$150,000	$250,000	31.3	$156,000	$306,000	30.6
Flood control	300,000	100,000	200,000	25.0	125,000	225,000	22.5
Power	600,000	250,000	350,000	43.7	219,000	469,000	46.9
Total	$1,300,000	$500,000	$800,000	100.0	$500,000	$1,000,000	100.0

In Table 2, Items 1 to 21 comprise a summary of the trial computations based on the alternative-justifiable-expenditure method for the successive steps in the TVA program of construction up to the close of fiscal year 1940 and including the Wilson, Wheeler, Norris, Pickwick Landing, Chickamauga, Guntersville, and Hiwassee developments. In Table 2, Items 22 to 34 are a summary of the final allocations for this same program as recommended by the Financial Policy Committee. It will be seen that the latter vary from the trial computations in Table 2, Items 1 to 21, by relatively small sums. This variation represents the factor of judgment that entered into the committee's consideration of the problem in making their final determination, as is explained subsequently. (Costs used in the three-plant allocation exclude $4,774,905 reserved for Wilson Dam depreciation from date of completion to date of acquisition by the Authority. In all subsequent allocations, total costs have been used—reconstruction cost new at Wilson—and depreciation reserves at all projects have been set up in a special account, independent of allocations.)

COMMENT

The allocation of the costs of the multiple-purpose projects is required by the TVA Act, which states that the cost of such projects shall be charged to flood control, navigation, fertilizer, national defense, and the development of power. It also requires that the findings of the allocation shall be used thereafter for the purpose of keeping the book value of these properties. Although not explicitly stated, it may be assumed that the reason Congress required such allocation was to determine equitable rates for the sale of power. This assumption is further borne out by the language of the same section of the Act concerning the keeping of accounts, which states that

> "* * * for the purpose of accumulating data useful to the Congress in the formulation of legislative policy in matters relating to the generation, transmission, and distribution of electric energy * * * the Board shall keep complete accounts of its cost of generation, transmission, and distribution of electric energy."

Although the allocations made thus far have not as yet been used in the actual setting of power rates, tentative allocations were used by the engineers of the Joint Investigating Committee, appointed by Congress, in their study of the power rates actually in effect. They found that these rates would produce revenues sufficient to retire more than all of the cost of generation, transmission, and distribution of power, including interest. In fact, without such an allocation of costs, it would have been nearly impossible for this study to have been made.[2]

The various theories of joint-cost allocation considered by the TVA Financial Policy Committee have been previously described herein. Arguments for and against such theories are of academic interest, since the real difficulties arise in their application.

Such difficulties constitute the real objection to the direct use of the benefit theory, so-called. This method appeals to engineers as being reasonable and equitable. It has long been used in assessing costs of irrigation, flood control, and land drainage, where the costs of the projects themselves are paid for by taxation on the real property served or protected.

A little reflection will convince any experienced engineer that the value of the benefits from the various components of the Authority's program cannot be estimated with sufficient accuracy to serve as the basis for accounting procedures. These benefits are very real and very considerable, but by their very nature include a wide variety of both tangible and intangible items that cannot be evaluated with any pretense of accuracy.

There is no real justification for basing the allocation of costs for accounting purposes upon any one mathematical formula. The principal method adopted by the Authority serves more as an aid to judgment than as a formula for the accurate determination of definite values.

By this method the common costs are allocated in proportion to the remaining costs resulting from the subtraction of direct costs from the total estimated alternative costs. This amounts to assuming that the savings from multiple-purpose development are shared in by the various purposes in this same proportion. It is also equivalent to allocating the common cost in proportion to the cost of constructing separately those facilities which in multiple-purpose development are provided by the jointly-used portions of the project.

---

[2] "Engineers' Report of the Joint Committee Investigating the Tennessee Valley Authority," S. Doc. No. 56, Pt. III, 76 Cong., 1st Session.

The exactness of such a method from the mathematical point of view depends upon the accuracy with which it is possible to estimate the cost of hypothetical "alternative" single-purpose developments. These estimates from the accounting standpoint have practically no accuracy at all, since they must depend upon broad assumptions regarding the design of such developments.

Nevertheless, these computations are a most valuable aid to the judgment in arriving at final allocations of cost, since they show the trends of different items, and the effect of the different and variable factors.

In the end, the actual allocation of costs must be an arbitrary and empirical process, and the writer can see no reason why this should not be recognized frankly. Since no one method has received any official or judicial approval, it is entirely reasonable to use any or all methods when these are appropriate and equitable.

Limits of Variation

It is pertinent to examine, at this point, the limits of variation in the final allocations as affected by the application of the theory. In the cost allocations the direct costs of the various purposes can be readily ascertained and are not subject to variations due to possible inaccuracies of estimates. The allocations based on the alternative-justifiable-expenditure theory, however, are affected by possible inaccuracies in the estimates of alternative costs. These possible inaccuracies have been held to a minimum in so far as possible in the allocations made thus far, since the costs which were used for alternatives were based largely on the costs of the multiple-purpose projects with comparatively minor alterations. Moreover, a comparatively large variation in the alternative costs would result in a minor variation in the final allocations as is demonstrated by Table 3, which shows the effect of variations made in the seven-plant allocation based on the alternative-justifiable-expenditure theory.

TABLE 3.—Relative Effect of Changes in Alternative Costs (Percentages)

Facility	Reduction in cost of one-purpose system[a]	Corresponding Change in the Allocation of Costs to Power	
		Common costs	Total costs
Navigation	10	+1.8	+1.1
Flood control	10	+1.1	+0.6
Power	10	−4.1	−2.6

[a] Other systems remain the same.

Viewing this problem in its broadest sense, it is evident that no allocation can be determined with mathematical precision. On the other hand, there are reasonable limits to the variations in allocations of common cost.

Where three major purposes are involved, it would be an obvious absurdity to charge more than half of the common cost to power alone, especially where power production is designated by congressional legislation as incidental to the other two purposes. On the other hand, where power is the only "paying partner," it is difficult to justify charging to power less than one third of the common costs in any event.

The TVA allocation of common costs to power has been set at 40% for the three-plant to seven-plant systems, resulting in an average allocation to power of the total costs of about 52%. Were the allocation of common costs increased from 40% to 50%, this would increase the total to only 58% whereas a decrease in allocation of the common costs from 40% to 33⅓% would reduce the total to only 48%.

The extreme reasonable range of the total allocation to power, regardless of the method adopted, therefore, is from 48% to 58%. Considering the difficulty of the problem and the wide divergence of opinion expressed in this connection, this is distinctly reassuring.

OTHER SIMILAR ALLOCATIONS

Bonneville Project.—Reference 6, in the Appendix, contains material quoted from the Federal Power Commission's release No. 380 with reference to the allocation of costs for the Bonneville project.

Boulder Power Plant.—The Swing-Johnson Bill, which provided for construction of Boulder project, required that before construction of the dam was started contracts should be engaged for sale of power at a price sufficient to repay the entire cost of the construction of the dam, together with interest at 4%, in a 50-yr period. The actual contracts as entered into with the various lessees provided that each shall pay a certain price for use of falling water at a dam, and that the cost of the power installation shall also be paid by these lessees at a rate sufficient to repay the cost of the power plant in 25 years, together with interest. These contracts are now in force and apparently the cost of the dam will be repaid as provided in the Act.

However, the City of Los Angeles, Calif., has endeavored to obtain a modification of the prices paid for power whereby a substantial allocation would be made to flood control, the cost of power equipment would be repaid in 50 years instead of 25, and the rate of interest on the investment would be reduced from 4% to 3%. This bill was passed by Congress in July, 1940.

CONCLUSIONS

The TVA allocation of costs may be summarized as follows:

1. The allocation was made as directed by Act of Congress;
2. Allocation is not based exactly on any one mathematical calculation or formula, the final sums being fixed by judgment and not by computation;
3. Items used solely for a particular purpose are charged to that purpose alone; it is therefore only the remaining "common costs" which require allocation;
4. A considerable variation in the allocation of common costs affects, to a much lesser degree, the proportions of the total cost charged to the three purposes; and
5. Because only the allocation of common costs is at all open to question, the possible variation in the totals due to different methods of allocation is

comparatively small. It can be shown, therefore, that the final allocations are approximately correct, within reasonable limits, regardless of the method adopted.

Most of the material used in the preparation of this paper, including estimates and similar data, was contributed by W. L. Voorduin, Assoc. M. Am. Soc. C. E., of the TVA engineering staff.

APPENDIX

DOCUMENT CITATIONS AND REFERENCES

Ref. 1.—Tennessee Valley Authority Act:

"Sec. 9*a*. The board is hereby directed in the operation of any dam or reservoir in its possession and control to regulate the stream flow primarily for the purposes of promoting navigation and controlling floods. So far as may be consistent with such purposes, the board is authorized to provide and operate facilities for the generation of electric energy at any such dam for the use of the Corporation and for the use of the United States or any agency thereof; and the board is further authorized, whenever an opportunity is afforded, to provide and operate facilities for the generation of electric energy in order to avoid the waste of water power, to transmit and market such power as in this act provided, and thereby, so far as may be practicable, to assist in liquidating the cost or aid in the maintenance of the projects of the Authority.

"Sec. 14. The board shall make a thorough investigation as to the present value of Dam Numbered 2, and the steam plants at nitrate plant numbered 1, and nitrate plant numbered 2, and as to the cost of Cove Creek Dam, for the purpose of ascertaining how much of the value or the cost of said properties shall be allocated and charged up to (1) flood control, (2) navigation, (3) fertilizer, (4) national defense, and (5) the development of power. The findings thus made by the board, when approved by the President of the United States, shall be final, and such findings shall thereafter be used in all allocations of value for the purpose of keeping the book value of said properties. In like manner, the cost and book value of any dams, steam plants, or other similar improvements hereafter constructed and turned over to said board for the purpose of control and management shall be ascertained and allocated.

"The board shall, on or before January 1, 1937, file with Congress a statement of its allocation of the value of such properties turned over to said Board and which have been completed prior to the end of the preceding fiscal year, and shall thereafter in its annual report to Congress file a statement of its allocation of the value of such properties as have been completed during the preceding fiscal year.

"For the purpose of accumulating data useful to the Congress in the formulation of legislative policy in matters relating to the generation, transmission, and distribution of electric energy and the production of chemicals necessary to national defense and useful in agriculture, and to the Federal Power Commission and other Federal and State agencies, and to the public, the Board shall keep complete accounts of its costs of generation, transmission, and distribution of electric energy and shall keep a complete account of the total cost of generating and transmission facilities constructed or otherwise acquired by the Corporation, and of producing such chemicals, and a description of the major components of such costs according to such uniform system of accounting for public utilities as the Federal Power Commission has, and if it have none, then it is hereby empowered and directed to prescribe such uniform system of accounting, together with records of such other physical data and operating statistics of the Authority as may be helpful in determining the actual cost and value of services, and the practices, methods, facilities, equipment, appliances, and standards and sizes, types, location, and geographical and economic integration of plants and systems best suited to promote the public interest, efficiency, and the wider and more economical use of electric energy. Such data shall be reported to the Congress by the board from time to time with appropriate analyses and recommendations, and, so far as practicable, shall be made available to the Federal Power Commission and other Federal and State agencies which may be concerned with the administration of legislation relating to the generation, transmission, or distribution of electric energy and chemicals useful to agriculture. It is hereby declared to be the policy of this Act, that, in order, as soon as practicable, to make the power projects self-supporting and self-liquidating, the surplus power shall be sold at rates which, in the opinion of the board, when applied to the normal capacity of the Authority's power facilities, will produce gross revenues in excess of the cost of production of said power and in addition to the statement of the cost of power at each power station as required by section 9 (*a*) of the 'Tennessee Valley Act of 1933,' the board shall file with each annual report a statement of the total cost of all power generated by it at all power stations during each year, the average cost of such power per kilowatt-hour, the rates at which sold, and to whom sold, and copies of all contracts for the sale of power."

Ref. 2.—"Rules of Practice and Regulations" of the Federal Power Commission (dated June 1, 1938), Section 11.22:

"Reasonable annual charges for recompensing the United States for the use of Government dams or other structures owned by the United States and for the use, occupancy, and enjoyment of the lands of the United States adjoining and pertaining thereto will be based upon the estimated value for power purposes of the properties and privileges for which a license is issued * * *."

Some examples of power facilities built by private companies subject to this provision are:

Company	River	Development
Henry Ford and Son, Inc.	Hudson	Green Island
Louisville Gas and Electric Company	Ohio	Dam No. 41
Ford Motor Company	Mississippi	Twin Cities
Kanawha Valley Power Company	Kanawha	Marnet, London, and Dam No. 1
Kentucky Utilities Company	Kentucky	Lock No. 7

Ref. 3.—The Third Annual Report of the Federal Power Commission (for the fiscal year ended June 30, 1923) states regarding Project No. 362 (Twin Cities Development), Section 7, p. 256:

"To recompense the United States for the use of said dam and appurtenant structures and lands adjoining and pertaining thereto, the license to pay as a reasonable annual charge the sum of $95,440 said sum being interest * * * and depreciation * * * upon $1,193,000 an amount deemed to be so much of the cost of said dam, structures, and lands as would be justified if built or purchased solely for purposes of power development."

Ref. 4.—H. Doc. No. 709, pp. 19–20:

"The concept of alternative cost is premised on the theory that the expenditure in single-use projects would be justified by the benefits obtainable; hence, the alternative cost may be taken as a measure of the investment which the individual purposes would be justified in expending in a joint venture. Where such a cost would not have been justified, it is necessary to substitute a lower estimate based on evaluation of the benefits.

"Through the medium of alternative costs, a relative measure of value applicable to all purposes is utilized. In applying this method it is necessary to secure estimates of the lowest alternative cost by means of which substantially the same quantity and quality of service for each separate function can be obtained. The fundamental assumptions which underlie the cost estimates for single-use structures must be as reasonable and practical as they can be made and must be based upon experience and after adequate investigation."

Ref. 5.—H. Doc. No. 709, p. 20:

"After a review and extensive exploration of all the relevant methods, the committee has reached the conclusion that no one method furnishes the best general basis upon which to proceed to a final allocation that would reflect the various shares of the total joint costs to be imposed on the several functions of the Wilson, Norris, and Wheeler projects. The committee recognizes that each of the relevant methods has a measure of validity under some circumstances but that there are objections to or difficulties in the application of all the methods to the Authority's projects. Much time and effort were devoted to testing out the various hypotheses involved on the existing and proposed projects of the Authority. The allocations finally recommended are admittedly based on an exercise of judgment after considering all facts; nevertheless the committee is unanimous in believing that they furnish a fair basis for determining the relative shares of the various functions in the joint costs."

With respect to the three-plant allocation, the committee further decided that:

"The three completed projects represent a great national-defense asset, but because they are not in operation for that purpose during peacetime, it appears to be impracticable to attempt to allocate any portion of the investment to their wartime use, and the committee recommends that no part of the investment be assigned to that function. It is further recommended that no part of the joint investment be allocated to fertilizer, since fertilizer operations are being currently charged for services rendered by other departments of the Authority."

Ref. 6.—Release No. 380, Federal Power Commission:

"The initial power development at Bonneville, which will have installed electric generating capacity of 86,400 kilowatts or approximately one-fifth of the probable ultimate installation, is slated for completion by June 30, 1938, at a total estimated cost, including interest during construction, of $9,180,500 for facilities solely for power purposes. The Commission has allocated this entire sum to initial power development and, in addition, has allocated $2,501,900 of the total estimated cost to June 30, 1938, of facilities having joint value for the purposes of navigation and power development.

"The $2,501,900 figure was obtained through the determination that, ultimately, power development may fairly bear 32.5 percent of the cost of facilities having joint value for the production of electric energy and other purposes. The total estimated cost of such facilities to June 30, 1938, including fishways, is $38,490,700 and the present allocation to initial power development is one-fifth of 32.5 percent of this sum.

"The total cost of the Bonneville project when completed is estimated at $74,144,600. In setting this figure, the Commission has estimated the cost of ultimate power development with ten generating units having an aggregate capacity of 504,000 kilowatts, together with the cost of all at-site appurtenant facilities for power use only, to be $29,448,000; and the cost of facilities having joint value for navigation and power purposes, including fishways, to be $39,179,000. It is estimated that the cost of facilities for navigation purposes only will be $5,517,600 as of June 30, 1938, and no additional capital costs for facilities solely for navigation purposes are contemplated.

"On the basis of the Commission's present determination that ultimately power development may fairly bear 32.5 percent of the cost of facilities having joint value for the production of electric energy and other purposes, $42,181,000 or approximately 57 percent, of the total ultimate cost of the Bonneville project would be allocated to power development."

DISCUSSION

Malcolm Elliott,[3] M. Am. Soc. C. E.—The author has made a convincing presentation of the desirability of using the alternative-justifiable-expenditure theory as a basis for the allocation of costs of multiple-purpose projects.

It is assumed that this theory of cost allocation is applicable to preliminary studies of a project, made for the purpose of determining whether a project or any feature of it is economically warranted, as well as to the allocation of the known total cost after the project is completed. As far as preliminary estimates of costs, budgeting appropriated funds, and final accounting of expended funds are concerned, it appears that the alternative-justifiable-expenditure theory forms as good a guide as any that can be devised for determining what proportion of the total estimated or expended funds should be allocated to the various purposes. However, there is another use that must be made of the cost allocations of the TVA projects in which it is questionable whether the alternative-justifiable-expenditure theory is properly applicable.

The author has quoted from the TVA Act (see heading "Comment"):

> "* * * for the purpose of accumulating data useful to the Congress in the formulation of legislative policy in matters relating to the generation, transmission, and distribution of electric energy * * * the Board shall keep complete accounts of its cost of generation, transmission, and distribution of electric energy."

This language, the debates in Congress, statements in committee hearings, and arguments in lawsuits involving the TVA leave little doubt that the intent of Congress was in part to create a "yardstick" by which rates charged by private power companies could be measured. It goes without saying that the "yardstick" itself should be fairly measured; otherwise the measurements made with it will be unfair either to the public or to the private companies.

An important element in the cost of production of power is the cost of financing, including interest, the sale of securities, and amortization to extinguish the investment at the end of the useful life of the project. Naturally, these costs will vary with the amount of the investment. The cost of a dam built for power alone must be carried entirely by power revenues, whereas the cost of a dam built for power, navigation, and flood control is divided among these three purposes. Hence, the capital expenditures for power are likely to be much less in the case of a government-built, multiple-purpose project than in the case of a privately built, single-purpose power plant. In the example used in Table 1, the first cost of a single-purpose power plant is $600,000, whereas a plant of equal capacity constructed as a part of a multiple-purpose project is but $469,000, or about 78% of a single-purpose plant.

The private owner, of course, would base his rates on a first cost of $600,000; but the government, if it employs the alternative-justifiable-expenditure theory advocated by the author, will measure the private company rates with a "yardstick" based on a first cost of $469,000, and therefore might conclude that as much of the private rates as depends on financing and interest charges should be reduced by 22%. The foregoing is merely an assumed numerical example; but, on examining the cost figures as computed for actual projects (Table 2), even greater disparities are found between the cost of single-purpose (alternative) power plants and power features included in multiple-purpose plants. For example, considering the three-plant system in Table 2, the alternative power cost is $79,230,000, whereas the final allocation of the multiple-purpose cost to power is but $49,360,179—roughly 62½% of the alternative cost.

---

[3] Col., Corps of Engrs., U. S. Army; Div. Engr., Upper Mississippi Val. Div., St. Louis, Mo.

Many people in the United States are favorable to production of power by the government on the theory that power is such a vital public necessity that its production should be at the lowest possible cost and not burdened with the earning of profits for private investors. If such theory were the established policy of the government, as determined by Congress, the government properly would take all possible advantage of its unique opportunity of combining power with public uses, such as navigation and flood control, in a way to reduce the first cost of power installations even though private companies were "run out of business." In the TVA Act, however, Congress has not adopted such a policy. The evident purpose of the Act is to make use of the power produced in connection with navigation and flood control works, to market the power in order to help defray the cost of such works, and to accumulate data useful to the Congress in the formulation of legislative policy relating to production and marketing of power.

It is the view of the writer that the allocation of costs based on the alternative-justifiable-expenditure theory, as described by the author, will fall short of furnishing Congress the data it will need for the formulation of policies unless it is clearly explained that the first costs of power installations thus computed are not for comparison with the necessary and reasonable costs that must be incurred by private companies for single-purpose power plants.

E. L. CHANDLER,[4] M. AM. SOC. C. E.—Proper allocation of the costs of multiple-purpose projects is a complicated problem, and the author has made a useful contribution to available data on the subject.

The alternative-justifiable-expenditure theory of allocation (see heading "Theories of Joint-Cost Allocations: Alternate Justifiable Expenditure) results in a solution that is applicable to most allocation problems. It appears to warrant more wholehearted approval than that accorded to it by the TVA Financial Policy Committee. In the introduction to its "Notes on Allocation," a supplement to the TVA formal report on cost allocations (H. Doc. No. 709, 75th Cong.), the Committee states that it "found most merit in the 'alternative-justifiable-expenditure' theory" and, in the last sentence of the paragraph on "Conclusion as to Allocation Theories," states that the "allocations finally recommended are admittedly based on an exercise of judgment after considering all facts."

A summary of allocations to date is given in Table 2. By comparing the percentages shown in items Nos. 18, 19, and 20 with corresponding values in items Nos. 31, 32, and 33, it will be noted that the exercise of judgment resulted in a change of 1.6% of the allocation to power in the three-plant system, as compared with the value determined by calculations based on the justifiable-expenditure formula. Changes in the allocations to navigation and flood control were 0.6% and 1.0%, respectively. The changes happen to have decreased step by step until, for the seven-plant system, there is an increase of only 0.7% of the allocation to power. It is scarcely reasonable to suppose that the accuracy of any allocation can be guaranteed within closer limits than these. Perhaps it is not exceeding the bounds of caution to say that the justifiable-expenditure method is the adopted method. There is merit in standardization if conditions warrant it.

---

[4] With Charles T. Main, Inc., Wilmington, Del.

Added confidence in the merit of this method is found in the fact that "it held its own," from the early days of allocation study, against all of the proposed methods, some of which were ardently supported by their sponsors. It was first used under the title of "benefit theory," and tentative allocations for the first four projects were prepared in 1936 and 1937. The term "benefit theory" was distasteful to some who were concerned with development of the allocations, chiefly because they did not find it possible to arrive at measures of benefits that seemed satisfactory to them. Later, with some changes in terminology and many improvements in details of the procedure used in deriving the estimated justifiable expenditures, but with no change in the application of the formula, the method emerged under the name "alternative-justifiable-expenditure" theory. The writer considers this to be very satisfactory nomenclature.

The maximum total justifiable expenditure for any one of the objectives served by a multiple-purpose project would be measured by the total benefit (with respect to the purpose under consideration) that is derived from the development of the project. Assuming that the value of benefits for any given objective exceeds the cost of the least expensive single-purpose project that might be devised for accomplishing equivalent results, the expenditure necessary for such a single-purpose project may be considered as a lower limit of justifiable expenditure. If the expenditure necessary for such a single-purpose project would not be justified by results to be accomplished, then a lower value for justifiable expenditure should be substituted. It should be some measure of the benefits to result from the expenditure.

The most suitable values to be used as "justifiable expenditures" in any given allocation problem may be determined in any one of several ways, as circumstances dictate. Perhaps a suitable measure of total benefits accruing to each of the purposes may be feasible. It may be found that values based on use of facilities afford a suitable basis, etc. In any event, the values used for all of the objectives of the problem at hand should be maintained on as nearly an equivalent basis as possible. In the TVA allocation, estimates for the cost of alternative single-purpose projects, deemed capable of providing services equivalent to that furnished by the multiple-purpose project, have been used for the purpose.

It is obvious that the accuracy of final allocations under this method depends largely on the soundness of estimates for the alternative justifiable expenditures. Assuming the adequacy of those estimates, the steps taken in developing the TVA allocation give results within what are, probably, suitable limits of accuracy, although they are not absolutely correct. During the allocation studies, methods of derivation were developed that lead to mathematically accurate results for all steps after original estimates have been established.

Method of Determining Directly Segregable Portions of Multiple-Purpose Project Costs.—For any multiple-purpose project, probably certain parts of the expenditures will have been made solely in the interests of specific objectives such as flood control, navigation, or power generation. It also will be true that certain parts of the structures serve more than one purpose. The first step in the problem of allocation is a determination of the directly segregable portions of the cost. A method for determining those segregable amounts has been developed geometrically and arithmetically as indicated in Fig. 2. This diagram and the following computations are intended to establish principles that may be applied to the solution of any given allocation problem:

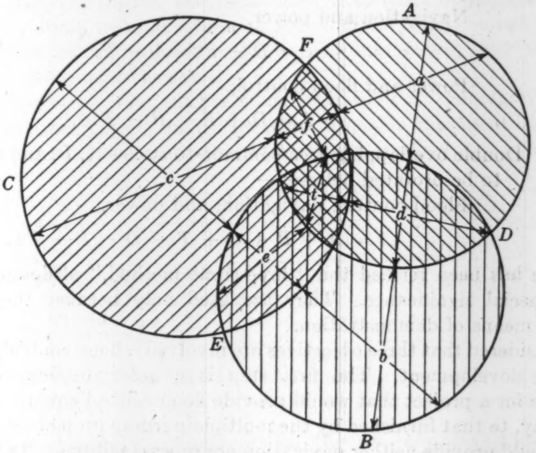

FIG. 2.—SEGREGATION OF DIRECTLY ALLOCABLE PARTS OF THE COST OF A MULTIPLE-PURPOSE PROJECT

Area (see Fig. 2)	Description
	Complete circle; total project cost if built for—
A	Flood control only
B	Navigation only
C	Power only
	Combined total project cost if built for—
D	Flood control and navigation (overlapping combination of areas *A* and *B*)
E	Navigation and power (overlapping combination of areas *B* and *C*)
F	Power and flood control (overlapping combination of areas *C* and *A*)
T	Flood control, navigation, and power (overlapping combination of areas *A*, *B*, and *C*; not indicated in Fig. 2)
	Part of circle not overlapped in combining the three circles is the cost directly allocated to—
a	Flood control,

$$a = T - E \qquad \text{(1a)}$$

b Navigation,

$$b = T - F \tag{1b}$$

c Power,

$$c = T - D \tag{1c}$$

Single overlapping area common to two circles is the cost to be prorated between—

d Flood control and navigation

$$d = E + F - C - T \tag{2a}$$

e Navigation and power,

$$e = D + F - A - T \tag{2b}$$

f Power and flood control,

$$f = D + E - B - T \tag{2c}$$

Double overlapping area common to circles *A*, *B*, and *C* is the cost to be prorated between—

t Flood control, navigation, and power,

$$t = A + B + C + T - D - E - F \tag{3}$$

This device has been termed the "three-circle method," although the circles have no special significance. They are used only because they furnish a convenient means of demonstration.

It is considered that three objectives are involved—flood control, navigation, and power development. The first step is a determination of justifiable expenditure for a project that would provide flood control equally satisfactory, in every way, to that furnished by the multiple-purpose project (area *A*, Fig. 2) but that would provide neither navigation nor power facilities. In like manner, the justifiable expenditure must be determined for a structure that would provide only for navigation equal to that furnished by the multiple-purpose project (area *B*, Fig. 2), and also for a single-purpose project (area *C*, Fig. 2) that would furnish the equivalent of power facilities included in the multiple-purpose development.

It is assumed that, if a dual-purpose project were built to provide for flood control and navigation, the resulting expenditure would be less than the combined sum represented by the total of areas *A* and *B*. Therefore, to represent such a dual-purpose project graphically, the two circles are shown overlapping in the diagram, and the combination is designated as area *D*, which is less than the total area *A* plus the total area *B* by the amount of overlapping (in this instance, indicated by the area *d* plus *t*). In the same way, if a dual-purpose project were to be built to serve the purposes of navigation and power, with no provision for flood control, the resulting expenditure is represented on the diagram by that part labeled *E*, which includes overlapping areas *B* and *C*. The net resulting sum in this case is less than the combined total of areas *B* and *C* by the amount of overlapping between the two areas, which is graphically represented by area *e* plus area *t*, Fig. 2. In the same way, a dual-purpose project built for purposes of flood control and power only is represented by the overlapping of area *A* and area *C*, the area being less than the combined total of *A* plus *C* by the amount of overlapping indicated by area *f* plus *t*. The three purposes are served at a cost materially less than would be the case if each of the three were to be gained by a single structure or if any combination of dual-purpose and single-purpose projects were developed.

Eqs. 1 to 3 will give the proper part of the total cost to be allocated directly to each of the three objectives; the part that is common solely to each combination of two objectives; and that part common to all three of the objectives. These values are fundamental, and allocation of the cost of the tri-purpose project is based on them.

In the case of a project involving more than three objectives, the method outlined would still be applicable. A fourth circle would be introduced and a larger number of simultaneous equations would result, but the principles involved would remain the same.

The discussion thus far has been purely theoretical. Segregation of the cost of a hypothetical project in accordance with the aforementioned theory is indicated arithmetically and diagrammatically in Fig. 3. The incremental costs are those expenditures made solely in the interest of single purposes. The first step in such a segregation is a determination of the justifiable expenditures for single-purpose projects that would have to be built to satisfy each one of the three objectives, and also for those projects that would serve each of the three dual combinations to an extent equal to the service rendered by the actual tri-purpose project. The following tabulation indicates the assumed cost of the project that would have resulted in each case:

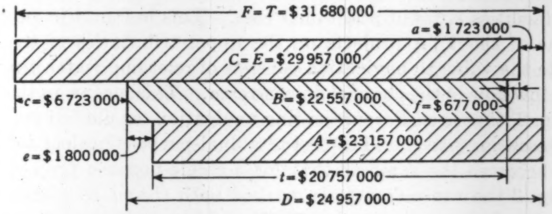

FIG. 3

Area (see Fig. 2)	Objective	Cost
A	Flood control only................	$23,157,000
B	Navigation only................	22,557,000
C	Power only......................	29,957,000
D	Flood control and navigation......	24,957,000
E	Navigation and power...........	29,957,000
F	Flood control and power..........	31,680,000
T	Total..........................	31,680,000

For the sake of clarity, in Fig. 2 the areas are shown overlapping by only small segments. As a matter of fact, in the case of most projects the cost common to two or more objectives is likely to be a large proportion of the total cost, and such a condition has been assumed for the hypothetical example. Then, it is difficult to indicate the true conditions to scale by the use of circles, and a different type of diagram has been devised in Fig. 3.

A study of this diagram will show that the cost of a project that would give flood-protection facilities equivalent to those assumed would be $23,157,000. Such a project would not be built in the interests of navigation or power development. This is indicated in Fig. 3 by the lower rectangle, length *A*. A project that would serve purposes of navigation only, without regard to flood control or to power, would cost $22,557,000 (length *B*, Fig. 3). The cost of a project built for purposes of power generation only would be $29,957,000 (length $C = E$, Fig. 3). The three rectangles have been arranged in a horizontal position such that the various other elements of cost desired are shown diagrammatically. For instance, if a dual-purpose project were built that would furnish flood-control and navigation facilities equivalent to those furnished by the tri-purpose project, but which would provide nothing specifically for power development, the cost would be $24,957,000. This is represented by length *D*.

The hypothetical tri-purpose project is such that, if a single-purpose project were built for the primary purpose of providing an equivalent of the existing power generation facilities, it would be sufficient also to provide the existing navigation facilities without additional cost. This is found to be true in the case of some of the TVA projects on the upper tributaries of the Tennessee River, where the value to navigation consists of releasing water during periods of normally low flow in the channel downstream. This means, in the case of the circles in Fig. 2, that area *B*, representing navigation, would fall entirely within area *C*, representing power. The cost of a dual-purpose project for navigation and power becomes the same as that for a single-purpose project for power. Thus, in Fig. 3 the top rectangle is marked both *C* and *E*. It also has been assumed that a dual-purpose project that would provide flood-control facilities and power-generation facilities equivalent to those now existing would be the same as the existing structure. Therefore, the combined dual cost represented by length *F* (Fig. 3) would be the same as the total cost of the existing project, *T* (= $31,680,000). The assumptions have been made with the purpose of setting up a rather complicated example.

Costs represented by lower-case letters and the overlapping of circles in the theoretical discussion have been determined as follows:

The cost directly allocable to flood control, represented by length *a*, is $1,723,000. In Fig. 3 it is represented by that part of the lower rectangle which extends beyond the right-hand limit of the upper rectangles. A project that would provide suitable power-generation facilities would automatically provide the necessary navigation facilities. Therefore, there is no part of the cost of the project to be allocated directly to navigation and, consequently, the value of *b* becomes zero. That part of the cost properly allocable solely to power generation, represented by length *c*, is $6,723,000. This is the part of the top rectangle which extends to the left beyond the limit of the lower rectangles. There is no value indicated for length *d* which, in the theoretical discussion, is that part of the cost common to flood control and navigation only. Considering only a dual-purpose project for purposes of flood control and navigation, the common element length *d* becomes $20,757,000. However, a dual-purpose project involving navigation and power would cost the same as a single-purpose project for power only. Thus, in Fig. 3, rectangle *B*, representing navigation, is completely overlapped by rectangle *C*, representing power, and it is evident that any part of the cost common to lengths *A* and *B* also must be common to length *C*. Therefore, the sum of $20,757,000, which is common to lengths *A* and *B*, actually becomes length *t* in this study (it is common to all three of the objectives), and *d* becomes zero. This means that no part of the cost is common to costs *A* and *B* which is not also common to cost *C*. That part of the cost common to navigation and power only (length *e*, Fig. 3) is $1,800,000. That part of the cost common to flood control and power only (length *f*, Fig. 3) is $677,000. The sum of $20,757,000, common to all three of the objectives, is shown as length *t* in Fig. 3.

The foregoing procedure appears to be mathematically correct. The fact that some of the values may prove to be zero has no bearing at all on the soundness of the method. The matter of resolving the total cost of a multiple-purpose project into the incremental costs directly allocable to the several objectives and into costs that are common is relatively simple if the foregoing procedure is followed. Dependability of the results obtained depends wholly on the accuracy with which the costs represented by the several capital letters are determined.

To segregate the costs for a tri-purpose project, it will be noted that estimates of cost for seven different projects may be required, although, as in the foregoing hypothetical case, the number may be reduced if two functions are served by a project built for any one of the objectives. In such a case a single-purpose project automatically assumes the character of a dual-purpose project.

During discussions of the allocation procedures, the estimating required in order to apply the method seemed to be a formidable objection to its use in the minds of some non-engineering members of the TVA staff. It does not appear too serious from an engineering viewpoint. Granting that any estimate is likely to be somewhat in error, carefully prepared estimates, formulated by experienced engineers, should fall within suitable limits of accuracy to satisfy the needs at hand. This is especially true when consideration is given to the relatively minor effect on ultimate allocations that may result from substantial variations in original estimates. This has been demonstrated by Mr. Parker in Table 3. The writer investigated these relations during the course of allocation studies and found that, on a basis substantially the same as the foregoing, with variations as large as 20% in the estimates of justifiable expenditures, the greatest change in allocation was approximately 4%, and the average was somewhat less than 2%. Careful estimates should not be more than 20% out of balance, and there seems little likelihood that allocations can be determined with any certainty of accuracy within 2%.

Method of Allocating Common Costs Under Alternative-Justifiable-Expenditure Theory.—The non-segregable costs common to more than one objective are determined under the "three-circle method" of segregation. In the cases studied, only tri-purpose projects are considered, although the same method of segregation and allocation may be applied to any multiple-purpose project.

In the "three-circle method" of segregation an "incremental cost" was determined for each of the three purposes, that being the expenditure incurred in each case over and above what would be expended if a dual-purpose project were built and the purpose under consideration were non-existent in the project. The costs common to each possible combination of two purposes were established on a basis of hypothetical dual-purpose projects, and the cost common to all three purposes was established.

After determining the "justifiable expenditure" for each objective, the segregated "incremental cost" is deducted, and the result becomes a sum that may be termed "justifiable additional investment." Having already charged to the objectives those parts of the multiple-purpose project costs that are directly segregable, it is logical to allocate the remaining common costs on the basis of "justifiable additional investments."

As described under the three-circle method of segregation, there are four items of common cost to be allocated. For exact allocation, each common cost should not be distributed directly on the basis of the "justifiable additional investments" with which it is concerned. Rather, each should be distributed in proportion to the remainders that would be left after the other three items of common cost have been allocated, and such allocations have been deducted from the corresponding "justifiable additional investments." The resulting amounts may be termed "remaining justifiable additional investments." The development of mathematical equations by which common costs may be directly allocated on this basis follows.

The following symbols are adopted to represent the quantities involved:

Symbol	Description
	Justifiable additional investment for—
M	Flood control
N	Navigation
O	Power
	Cost common to (see Eqs. 2 and 3)—
d	Flood control and navigation only
e	Navigation and power only
f	Power and flood control only
t	Flood control, navigation, and power
	Proportion of d allocated to—
d_m	Flood control
d_n	Navigation
	Proportion of e allocated to—
e_n	Navigation
e_o	Power
	Proportion of f allocated to—
f_m	Flood control
f_o	Power
	Proportion of t allocated to—
t_m	Flood control
t_n	Navigation
t_o	Power

Allocation of t.—The steps in the allocation of cost t are shown in Table 4(*a*). The total common cost t is to the part of t to be allocated to flood control

(t_m) as the total "remaining justifiable additional investment" is to the remaining justifiable additional investment for the part allocated to flood control.

TABLE 4.—Allocation Formulas; Justifiable Additional Investment

Justifiable additional investment	(a) Allocation of t		(b) Allocation of d		(c) Allocation of e		(d) Allocation of f	
	Previously allocated[a]	Breakdown	Previously allocated[a]	Breakdown	Previously allocated[a]	Breakdown	Previously allocated[a]	Breakdown
M	$d_m + f_m$	t_m	$f_m + t_m$	d_m	....	....	$d_m + t_m$	f_m
N	$d_n + e_n$	t_n	$e_n + t_n$	d_n	$d_n + t_n$	e_n	....	....
O	$e_o + f_o$	t_o	....	....	$f_o + t_o$	e_o	$e_o + t_o$	f_o
$M+N+O$	$d + e + f$	t	$e_n + f_m + t_m + t_n$	d	$d_n + f_o + t_n + t_o$	e	$d_m + e_o + t_m + t_o$	f

[a] Items considered as if previously allocated.

Expressing this proportion algebraically and transposing t to solve for t_m:

$$t_m = t \frac{M - (d_m + f_m)}{(M + N + O) - (d + e + f)} \quad \text{(4a)}$$

Similarly, the total common cost t is to the part of t allocated to navigation (t_n) as the total remaining justifiable additional investment is to the remaining justifiable additional investment for the part allocated to navigation; thus:

$$t_n = t \frac{N - (d_n + e_n)}{(M + N + O) - (d + e + f)} \quad \text{(4b)}$$

Finally, the total common cost t is to the part of t allocated to power (t_o) as the total remaining justifiable additional investment is to the remaining justifiable additional investment for the part allocated to power:

$$t_o = t \frac{O - (e_o + f_o)}{(M + N + O) - (d + e + f)} \quad \text{(4c)}$$

Allocation of d.—Since it is common to M and N only (see Table 4(*b*)), d is broken down into d_m and d_n. This eliminates line O, and the comparable equations are—

For flood control:

$$d_m = d \frac{M - (f_m + t_m)}{(M + N) - (e_n + f_m + t_m + t_n)} \quad \text{(5a)}$$

and, for navigation:

$$d_n = d \frac{N - (e_n + t_n)}{(M + N) - (e_n + f_m + t_m + t_n)} \quad \text{(5b)}$$

Allocation of e.—In this case, e is common to N and O only (see Table 4(*c*)) and therefore is broken down into e_n and e_o. Line M is thus eliminated and—

For navigation:

$$e_n = e \frac{N - (d_n + t_n)}{(N + O) - (d_n + f_o + t_n + t_o)} \quad \text{(6a)}$$

and, for power:

$$e_o = e \frac{O - (f_o + t_o)}{(N + O) - (d_n + f_o + t_n + t_o)} \tag{6b}$$

Allocation of f.—Being common to M and O only (see Table 4(d)), f is divided into f_m and f_o. This eliminates N, the justifiable additional investment for navigation. The remaining formulas are—

For flood control:

$$f_m = f \frac{M - (d_m + t_m)}{(M + O) - (d_m + e_o + t_m + t_o)} \tag{7a}$$

and, for power:

$$f_o = f \frac{O - (e_o + t_o)}{(M + O) - (d_m + e_o + t_m + t_o)} \tag{7b}$$

Major Equations.—First eliminate Eqs. 4 by substitution. For simplicity these may be written:

$$t_m = \frac{t}{K} (M - d_m - f_m) \tag{8a}$$

$$t_n = \frac{t}{K} (N - d_n - e_n) \tag{8b}$$

and

$$t_o = \frac{t}{K} (O - e_o - f_o) \tag{8c}$$

in which

$$K = (M + N + O) - (d + e + f) \tag{9}$$

In Eq. 5a (for example), substitute the values of t_m and t_n defined by Eqs. 8, and simplify the resulting form algebraically to

$$d_m = d \left[\frac{L\,(M - f_m) + t\,d_m}{L\,(M + N - e_n - f_m) + t\,d} \right] \tag{10}$$

in which $L = K - t$. Eq. 10 may be simplified further to the general formula:

$$d_m\,(M + N - e_n - f_m) = d\,(M - f_m) \tag{11}$$

Similarly, Eqs. 8 substituted in Eq. 6a yield (simplified algebraically)—

$$e_n = e \left[\frac{L\,(N - d_n) + t\,e_n}{L\,(N + O - d_n - f_o) + t\,e} \right] \tag{12}$$

which may be simplified to the general formula

$$e_n\,(N + O - d_n - f_o) = e\,(N - d_n) \tag{13}$$

In Eq. 7b, substitute t_o and t_m from Eqs. 4 to yield

$$f_o = f \left[\frac{L\,(O - e_o) + t\,f_o}{L\,(M + O - d_m - e_o) + t\,f} \right] \tag{14}$$

or

$$f_o\,(M + O - d_m - e_o) = f\,(O - e_o) \tag{15}$$

Eqs. 11, 13, and 15 can be written in the following form:

$$(M + N - f + f_o - e_n)\, d_m = d\,(M - f + f_o) \ldots\ldots\ldots (16a)$$

$$(N + O - d + d_m - f_o)\, e_n = e\,(N - d + d_m) \ldots\ldots\ldots (16b)$$

and

$$(O + M - e + e_n - d_m)\, f_o = f\,(O - e + e_n) \ldots\ldots\ldots (16c)$$

Solving Eq. 16*c* for f_o and substituting this value in Eqs. 16*a* and 16*b*, successively:

$$\begin{aligned} d_m\,[(O + M - e + e_n - d_m)\,(M + N - e_n - f) + f\,(O - e + e_n)] \\ = d\,[(O + M - e + e_n - d_m)\,(M - f) + f\,(O - e + e_n)] \ldots (17a) \end{aligned}$$

and

$$\begin{aligned} e_n\,[(O + M - e + e_n - d_m)\,(N + O - d + d_m) - f\,(O - e + e_n)] \\ = e\,[(N - d + d_m)\,(O + M - e + e_n - d_m)] \ldots\ldots\ldots (17b) \end{aligned}$$

The foregoing derivations have been given in considerably more detail than is necessary to obtain the results but the full procedure is given for the sake of clarity. Beyond Eqs. 17, further modification is inadvisable. By substituting known quantities in these formulas, solutions of d_m and e_n may be obtained. It is then a simple matter to derive allocations of the other common costs by substituting those values in preceding equations. Frequently, some one or more of the hypothetical dual-purpose projects contains no cost that is common only to the two objectives used in combination (that is, d, e, or $f = 0$). Under such circumstances, Eqs. 17 become much simplified. If desired, answers may be obtained by a graphic solution of the equations. In some instances the graphic method will be found to be preferable.

"Cut-and-Try" Solution.—The foregoing equations give results that are mathematically accurate. However, in most instances it is possible to arrive at results that are within satisfactory limits of accuracy by using a cut-and-try method of solution, which involves considerably less work without departing from the fundamental principles of the equations.

As a first step in the cut-and-try method, d, e, and f are broken down in direct proportion to the "justifiable additional investments," M, N, and O. This gives a set of tentative allocations for d, e, and f. Based on these values, a set of tentative "remaining justifiable additional investments" is obtained. These form a basis for a tentative allocation of t. Then the latter allocated values (t_m, t_n, and t_o) exchange places with the tentative breakdown of one of the first three common costs (say f), and a second set of "remaining justifiable additional investments" is obtained. Based on these, f is reallocated.

Following a similar procedure, the latest allocated values (f_o and f_m) now exchange places with the tentative values for e, and a new allocation for e is determined. Extending the process another step, d is reallocated. This completes a cycle that furnishes a new breakdown for each of the common costs. By the nature of the process these values are closer to a true allocation of the common costs than those first used.

It will be noted that these tentative allocations have been based on "remaining justifiable additional investments," but that the latter are not those which would result from deducting the true allocations from the original "justifiable additional investments."

Based on these allocations, other cycles are computed. With each cycle the adjustment in allocations becomes less and less as the true values are approached. The process is continued until the adjustments fall within desired limits of accuracy.

A hypothetical example is presented in Table 5, in which each of the aforementioned steps are shown. Nine cycles were used in order to study the rate at which the adjustment in the allocation values diminished. Computations for cycles intervening between the second and ninth are omitted since they add little to clarifying the procedure. Completion of the fourth cycle brought the allocation into such close agreement with the true values that further work was not justified with the small gain in accuracy. Hence, four cycles are deemed sufficient for a practical application of the method. In practice it is possible to omit the values of t and solve for d, e, and f; but, as in the development of the fundamental equations, all of the steps are included for the sake of clarity.

This cut-and-try method was found to be very satisfactory in the solution of the problem. A check may be made on the calculations at any time, and the work stopped after the degree of accuracy justified has been obtained. The variation of results obtained by each cycle indicates the rate at which the allocation values are approaching correctness. By studying these reductions it is readily possible to determine when the results have reached a point beyond which the refinement gained makes further calculations unnecessary.

The foregoing demonstration develops a mathematically correct method of allocating the joint or common costs in any multiple-purpose project, although in most instances it may be found that the increase in accuracy which is gained by the refinements of allocating the costs common only to two objectives (d, e, and f in the equations) is not of sufficient consequence to justify the work required. Under such circumstances it should be sufficient to allocate all of the joint costs ($d + e + f + t$) in one operation in proportion to the "justifiable additional expenditures" and to omit the other steps.

Acknowledgment.—The fundamentals of the foregoing mathematical derivations were proposed by Sherman M. Woodward, M. Am. Soc. C. E., chief water control planning engineer, under whose direction the writer acted as chief estimator in the TVA organization.

EUGENE L. GRANT,[5] M. AM. SOC. C. E.—Once a multiple-purpose project is completed, it may be operated in various ways. The demands of flood control for empty reservoirs and of power for full reservoirs are particularly in conflict. If a project really is operated with flood control as a primary objective and power a secondary one, the firm power generated may be only a small fraction of that obtainable with operation for power as a primary or coördinate objective. This may be true even though the method of operation may not have much effect on the average annual kilowatt-hours of energy generated.

The alternative-justifiable-expenditure method of cost allocation must necessarily be based on some assumed scheme of reservoir operation. This, in turn, determines the alternative plant and the alternative cost. Thus different prospective plans of operation will involve some differences in the costs allocated among the various purposes. However, it seems probable that—in some multiple-purpose projects, at least—the differences in benefits to the several purposes of the project with various plans of operation will be much greater than the differences in costs allocated to these purposes. This may be particularly evident where the value of firm power from one plan of operation is compared with the value of surplus power from some other plan. It would be interesting if, in his closure, Mr. Parker would comment on this point in relation to the TVA cost allocation study. Were cost allocations made for more than one plan of operation? If so, were allocated costs compared with benefits, and particularly power costs with power values, under the various plans?

Whatever the prospective plan of operation adopted in the design of a multiple-purpose project, it seems likely that circumstances will operate to cause departures from this plan. For instance, under war-time conditions of power shortage in the Tennessee Valley, it would seem reasonable to give major consideration to power in operating TVA reservoirs. In more normal times, the pressures on the operators of government multiple-purpose projects are likely to be strongest from those beneficiaries of the projects who make no special contribution to their costs—that is, from flood control and navigation interests. In this connection the propensity of congress to designate multiple-purpose projects as primarily for flood control and navigation regardless of their real justification may prove to be unfortunate. The Central Valley project in California, conceived as an irrigation project to be financed in large part from sale of power, but designated by congress as primarily a navigation and flood control project, is a case in point.

---

[5] Prof. of Economics of Eng., Stanford Univ., Dept. of Civ. Eng., Stanford University, Calif.

Sherman M. Woodward,[6] **Hon. M. Am. Soc. C. E.**—For many people the best approach to the allocation problem is from the point of view of the most reasonable distribution of the joint savings or profits in a multiple-purpose project. The data given in Table 1 are most convenient to illustrate this approach. Here a triple-purpose project for navigation, flood control, and power is assumed to cost only $1,000,000, whereas the justifiable expenditure for the three purposes, planned separately (see Col. 2, Table 1), totals $1,300,000. Thus, there is a savings or profit of $300,000 due to combining the three facilities in a joint undertaking rather than building them independently of each other. The amount saved is then allocated to each purpose so as to reduce the amount of the investment charged to each, as illustrated in Table 6. The final allocated cost values shown in Table 6 are the same as in Table 1.

TABLE 6.—Assumed Allocation of $1,000,000

Facility (1)	Justifiable investment (2)	Direct costs (3)	Remaining justifiable investment[a] (4)	Percentage of total (5)	Allocation of joint savings (6)	Allocated cost[b] (7)	Percentage of total (8)
Navigation.........	$400,000	$150,000	$250,000	31.3	$94,000	$306,000	30.6
Flood control.......	300,000	100,000	200,000	25.0	75,000	225,000	22.5
Power.............	600,000	250,000	350,000	43.7	131,000	469,000	46.9
Total..........	$1,300,000	$500,000	$800,000	100.0	$300,000	$1,000,000	100.0

[a] Col. 2 minus Col. 3. [b] Col. 2 minus Col. 6.

The allocation of joint costs seems to be a matter of accounting rather than of economics. It resembles somewhat the making of appraisals—a common procedure in connection with condemnation cases, bankruptcy cases, inheritance cases, insurance settlements, and damage cases, as well as in commercial transactions of all kinds. It requires knowledge, experience, and judgment in making the voluminous computations.

In the method of allocation used in Table 2, if one takes the difference between the columns for the seven-plant system and the six-plant system in an attempt to find the effect of the Hiwassee project, Items 2 and 10 seem to show that the justifiable investment in Hiwassee for the benefit of navigation is $1,000,000, whereas Items 14 and 18 seem to show that the actual computed allocation of the Hiwassee investment to navigation is $1,674,439. Of course, it was not intended that Table 2 should be used in this way, but if any one thinks that this is an important question, it is a simple matter to modify slightly the method of making the computation and remove the apparent inconsistency, as is illustrated in Table 7.

This table includes the first 21 items for part of the columns of Table 2. To simplify the presentation, all of the amounts stated in dollars have been changed to the nearest hundred thousand and then the last five ciphers are omitted. Col. 7, obtained by subtracting Col. 3 from Col. 5, shows that the total investment in Hiwassee to be allocated is $17,000,000; the total justifiable investment is $23,100,000; and the total direct costs amount to $3,400,000. This leaves $13,600,000 of common costs to be allocated, whereas the total remaining justifiable investment is $19,700,000. Col. 9 shows that if the common costs in Hiwassee are allocated in proportion to the components of the remaining justifiable investment in the Hiwassee project, finally the total investment in the Hiwassee project would be allocated approximately as follows: $700,000 to navigation, $7,700,000 to flood control, and $8,600,000 to power. Compared with the results in Col. 7, the figures in Col. 9 show about $1,000,000 less charged to navigation, $1,000,000 additional charged to flood control, and no change in the charge to power.

Albert R. Arledge,[7] **M. Am. Soc. C. E.**—Mr. Parker has made an interesting and useful presentation of the theories of allocation for general application as well as specifically for the TVA. The writer believes that many engineers have been puzzled as to how the various costs were determined for each element in a multiple-purpose project. This paper, the writer feels, has been helpful in clearing away the mist that formerly hung over such projects.

Under the heading "Other Similar Allocations," the author includes Boulder Power Plant. The writer is interested in presenting a fuller and clearer picture of this project in regard to allocations. A thorough treatment of this subject would be too long and involved. Consequently, only a few of the selected high lights that bear on the financing will be treated.

The Boulder Canyon project and other major multiple-purpose projects are fairly similar in the purposes for which they were constructed—that is, to improve navigation, control floods, store water for irrigation and domestic supply, generate electrical energy, etc.—and in allocations made for the different functions. They are dissimilar when it comes to the financing or repayment to the government of the cost of the various projects. In different localities different functions receive emphasis. For example, the flood control and water conservation features were emphasized in the publicity advocating the passage of the Boulder Canyon Project Act, but power was selected to make the project "a self-supporting and financially solvent undertaking."

The principal reason for the lack of uniformity in public policy regarding these large projects is probably the fact that the Boulder Canyon Project Act was passed in December, 1928, before the Depression and the great wave of unemployment swept the United States, whereas the other projects were authorized subsequently to this crisis in a constructive attempt to reduce unemployment and improve labor conditions. In any event, between the time of enactment of the Boulder Canyon Project Act and the setting up of other multiple-purpose projects, the Congress changed its public policy from that of requiring self-liquidation to that of granting financial aid by allocating federal funds to functions other than power. These funds ranged from 67.5% to 43% of the ultimate cost of the Bonneville project and from 60% to 48% of the ultimate cost in the case of the TVA. Power is not obligated to repay such allocations. Power at Boulder Dam is obligated to repay all costs of the project, including the allocation to flood control.

Attention is directed to the fact that the Congress of the United States set public policy by the terms of the Boulder Canyon Project Act,[8] approved December 21, 1928, when it authorized the Secretary of the Interior, in Section 1, in part, as follows:

> "* * * for the purpose of controlling the floods, improving navigation and regulating the flow of the Colorado River, providing for storage and for the delivery of stored waters thereof for the reclamation of public lands and other beneficial uses exclusively within the United States, and for the generation of electrical energy as a means of making the project herein authorized a self-supporting and financially solvent undertaking, * * * subject to the terms of the Colorado River Compact herein men-

[7] Prin. Civ. Engr., Los Angeles Bureau of Power & Light, Los Angeles, Calif.

[8] "Boulder Canyon Project Act," *Public No. 642*, H. R. 5773, 70th Cong., 2d Session.

> tioned * * * to construct, operate, and maintain a dam and incidental works in the main stream of the Colorado River at Black Canyon or Boulder Canyon adequate to create a storage reservoir of a capacity of not less than twenty million acre-feet of water * * *: Provided * * * also to construct and equip, operate, and maintain at or near said dam, or cause to be constructed, a complete plant and incidental structures suitable for the fullest economic development of electrical energy from the water discharged from said reservoir * * *."

Although the foregoing section authorized the Secretary of the Interior to construct the Boulder Canyon project, it was necessary to meet the further provision of financing before work could proceed legally. This provision follows:

> "Sec. 4(b). Before any money is appropriated for the construction of said dam or power plant, or any construction work done or contracted for, the Secretary of the Interior shall make provision for revenues by contract, in accordance with the provisions of this Act, adequate in his judgment to insure payment of all expenses of operation and maintenance of said works incurred by the United States and the repayment, within fifty years from the date of the completion of said works, of all amounts advanced to the fund under subdivision (b) of Section 2 for such works, together with interest thereon made reimbursable under this Act." [8]

The "Project Act" makes an allocation for flood control purposes. C. C. Elder,[9] M. Am. Soc. C. E., has given the background of this project in greater detail than can be given herein. To quote Mr. Elder on this subject:

> "All advances to the Colorado River Dam fund from the U. S. Treasury were required to be repaid with four per cent interest, but a definite allocation of $25,000,000 was made to flood control to be repaid out of 62.5 per cent of excess revenues, if and when available. If this repayment were not completed within the general 50-year amortization period, ending May 31, 1987, repayment was to be continued out of the same proportion of the project's net revenues. Thus deferment was permissible for the flood control allocation's repayment, if this became necessary, but provision was made for full repayment finally, with four per cent compound interest. The amount of this flood control allocation appears to have been fixed arbitrarily, so far as is now evident, but is approximately the sum that might have been needed for a program of flood control by means of a low dam for this purpose solely, and a system of raised and strengthened levees. This solution would have given immediate, but evidently only temporary, relief from flood damages, due to relatively rapid filling with silt of a small reservoir. But the federal obligation to furnish some degree of flood control on the lower Colorado River was recognized, and this is probably the only case to date where repayment, even though possibly on a deferred basis, of a government flood control structure, or its allocated share of the construction cost, has ever been required or promised.
>
> "In addition to the flood control allocation, other excess revenues of the Colorado River Dam fund were allotted as follows:
>
> > " 'If during the period of amortization the Secretary of the Interior shall receive revenues in excess of the amount necessary to meet the periodical payments to the United States as provided in the contracts executed under this act, then, immediately after the settlement of such periodical payments, he shall pay to the State of Arizona 18¾%

---

[9] "Boulder Canyon Project, Original and Readjusted Repayment Contracts," by C. C. Elder—presented before the Engineering Economics Division, Am. Soc. C. E., 89th Annual Meeting, New York, N. Y., January 22, 1942.

> of such excess revenues and to the State of Nevada 18¾% of such excess revenues.
>
> "'After the repayments to the United States of all money advanced with interest, charges shall be on such basis and the revenues derived therefrom shall be kept in a separate fund to be expended within the Colorado River Basin as may hereafter be prescribed by the Congress.'
>
> "Records of Congressional Committee hearings indicate that the intent of Congress was that Arizona and Nevada should receive some payments in lieu of taxes which would have been levied if the project had been privately developed. The amount is stated as having been arrived at on the basis of a fairly parallel case, the leasing of public oil lands, where the rule had become established that the State involved should receive 37 per cent of the net revenue in lieu of taxes. The disposition of the balance of excess revenues, after completion of repayment of U. S. Treasury advances to the fund, was such a remote problem as not to excite immediate interest, so that it was merely left to future action of Congress, though allotted for Colorado River Basin developments if and when available."

In compliance with the foregoing authorization and provisions, the Secretary of the Interior, after investigation and study of regional market conditions, set a schedule of rates in Article (16) of the contract, dated April 26, 1930, a part of which follows:

> "(16) In consideration of this lease, the lessees severally agree:
>
> "(1) To pay the United States for the use of falling water for the generation of energy for their own use, respectively, by the equipment leased hereunder (except as otherwise provided in Article Seventeen (17) hereof), as follows:
>
> "(*a*) One and sixty-three hundredths mills ($0.00163) per kilowatt-hour (delivered at transmission voltage) for firm energy;
>
> "(*b*) One-half mill ($0.0005) per kilowatt-hour (delivered at transmission voltage) for secondary energy; * * *.
>
> "At the end of fifteen (15) years from the date of execution of this contract and every ten (10) years thereafter, the above rates of payment for firm and secondary energy shall be readjusted upon demand of any party hereto, either upward or downward as to price, as the Secretary (of Interior) may find to be justified by competitive conditions at distributing points or competitive centers."[10]

Based on the rates established in the aforementioned contracts, prepared and executed under the original act, the two lessees, the Los Angeles Municipal Bureau of Power and Light and the Southern California Edison Company, Ltd., assumed the financial responsibility for the return of the full costs of the dam, power house, and incidental structures in 50 years at 4% interest, and for the return of the cost of machinery and equipment in ten annual installments, as set up in Article (9)(a) of the contract which, in part, follows:

> "(9)(a) Compensation for the use, for the periods of lease thereof, of machinery and equipment furnished and installed by the United States, for each lessee respectively, for the generation of electrical energy, equal to the cost thereof, including interest charges at the rate of four per centum (4%) per annum, compounded annually from the date of advances to the

---

[10] Contract for Generation and Transmission of Power, Boulder Canyon Project—Bureau of Reclamation, U. S. Dept. of the Interior; the City of Los Angeles, Calif.; and Southern California Edison Company, Ltd., April 26, 1930.

> Colorado River Dam Fund for the purchase of such equipment and machinery to June 1st of the year next preceding the year when the initial installment becomes due under this article, shall be paid to the United States by the lessees, severally, in ten (10) equal annual installments, so as to amortize the total cost (including interest as fixed above), and interest thereafter upon such total cost at the rate of four per centum (4%) per annum * * *."[10]

The power obligation of these two lessees totaled 64% of the firm power (this included the 18% allotment to each of the states of Arizona and Nevada, divided equally between the two lessees). The states assumed no financial responsibility in regard to the capital outlay. At that time, the Metropolitan Water District of Southern California, whose allotment was 36% of the Boulder Dam firm energy, was not considered a going concern, as the bonds for the construction of its Colorado River Aqueduct had not yet been voted.

From the preceding sketchy review of the requirements and provisions of the Project Act and the contracts, and the additional fact that the Metropolitan Water District long since had voted its bonds and had become a going concern, it would seem apparent that a revision of the contracts was necessary to maintain justice and equity between the government and the lessees.

The Boulder Canyon Project Adjustment Act[11] permits the contracts for energy to be adjusted to rates more comparable with the liberal public policy adopted by the Congress for other multiple-purpose projects throughout the United States. It recognized 100% power allotment for amortization purposes instead of 64% of the allotment as set in the original contracts. The "Adjustment Act" also provides more certain payments to the states of Arizona and Nevada and to the Colorado River Development Fund.

The Secretary of the Interior was interested, from an administration standpoint, in changing the lessee from a "Contract for Lease of Power Privilege" to that of an "Agent of the United States for the Operation of the Power Plant." The Adjustment Act provided the mechanics under which the desirable changes suggested could be made. The adjusted rates for Boulder Dam energy will more nearly meet "competitive conditions at distributing points or competitive centers," will still comply with the rigorous requirements of the original Act for a self-supporting project, and will reduce the initial rates roughly 30%.

Under "Limits of Variation" the author has well stated:

> "Viewing this problem in its broadest sense, it is evident that no allocation can be determined with mathematical precision. On the other hand, there are reasonable limits to the variations in allocations of common cost.
>
> "Where three major purposes are involved, it would be an obvious absurdity to charge more than half of the common cost to power alone, especially where power production is designated by congressional legislation as incidental to the other two purposes. On the other hand, where power is the only 'paying partner,' it is difficult to justify charging to power less than one third of the common costs in any event."

The writer feels that the author, in these two paragraphs, has expressed a policy in regard to allocations which could well be adopted by the Congress as a guide to simplicity and uniformity in public policy for the benefit of all multiple-purpose projects that it initiates.

---

[11] "The Boulder Canyon Project Adjustment Act," approved July 19, 1940, *Public No.* 756, H. R. 9877, 76th Cong., 3d Session.

In summarizing, the Adjustment Act has effected changes, as follows:

1. Lessee to operating agent;
2. 4% interest to 3% interest;
3. (*a*) The rate for firm energy from 1.63 mills per kw-hr to 1.163 mills per kw-hr; and (*b*) the rate for secondary energy from 0.50 mill per kw-hr to 0.34 mill per kw-hr;
4. Payment for machinery and equipment from ten annual installments to 50 years;
5. The postponement of the payment of the flood control allocation without interest until the end of the 50-yr amortization period, May 31, 1987;
6. The payments of 18¾% of

> "* * * revenues in excess of the amount necessary to meet the periodical payments to the United States as provided in the contract, or contracts, executed under this Act * * *"[8]

if any, to each of the states of Arizona and Nevada, to the payment

> "* * * to each of said States of the sum of $300,000 for each year of operation, beginning with the year of operation ending May 31, 1938, and continuing annually thereafter until and including the year of operation ending May 31, 1987 * * *"[11]; and

7. The payment for the Colorado River Basin development changed from the stipulation that

> "* * * after the repayment to the United States of all money advanced with interest, charges shall be on such basis and the revenues derived therefrom shall be kept in a separate fund to be expended within the Colorado River Basin as may hereafter be prescribed by the Congress,"[8]

to a more assured and earlier payment, as defined by:

> "* * * the sum of $500,000 for the year of operation ending May 31, 1938, and the like sum of $500,000 for each year of operation thereafter, until and including the year of operation ending May 31, 1987 * * *."[11]

Items 6 and 7 are subject to a further provision as set forth in Section 3 of the Adjustment Act, as follows:

> "If, by reason of any act of God, or of the public enemy, or any major catastrophe, or any other unforeseen and unavoidable cause, the revenues, for any year of operation, after making provision for costs of operation, maintenance, and the amount to be set aside for said year for replacements, should be insufficient to make the payments to the States of Arizona and Nevada and the transfers to the Colorado River Development Fund herein provided for, such payments and transfers shall be proportionately reduced, as the Secretary may find to be necessary by reason thereof."[11]

An unusual feature of the Adjustment Act is its retroactive character, requiring these changes to become effective June 1, 1937.

C. W. WATCHORN,[12] ESQ., AND F. A. ALLNER,[13] M. AM. SOC. C. E.—The problem of allocating the cost of an enterprise to the various services it renders or to the commodities it produces is difficult, even when the services rendered or the commodities produced are all of the same general kind. The problem of allocation is still more complicated for multiple-purpose enterprises or projects of which the services or products are of very different kinds.

Strictly speaking, the so-called theories of joint-cost allocations, with the possible exception of the use-of-facilities theory, are never actually what their names indicate; rather, they are mathematical methods that arbitrarily assign responsibility for the joint cost to the various purposes of a project. These cost-allocating methods are just as applicable to a single-purpose project with respect to the various users of its services as to a multiple-purpose project with respect to its various purposes. It is not difficult to imagine situations where, for a single-purpose project, the application of these cost-allocation theories would lead to inequitable and discriminative results. There are many cases in which the cost of obtaining a given service in one way has no conceivable relation to the cost of obtaining it in another way; for example, the customers of a water utility may be able to supply their own requirements privately at varying unit costs, depending on their respective circumstances. There is no basis for assuming that the cost to the utility to supply these various customers would bear any relation to the costs to such users to supply themselves. Since the application of the alternative cost or of any other method may lead to arbitrary and discriminative results when applied to such a relatively simple case, it follows that the same result may be obtained when these same methods are applied to the more complicated problem of allocating cost for multiple-purpose projects. As stated by the author, however, the more generally accepted methods for allocating the cost of a single-purpose project scarcely would be adaptable to a multiple-purpose project because of the absence of common characteristics of the services of the various purposes of such projects.

Even for electric utilities, there is no one generally accepted method for allocating cost to the various classes of customers. The reason that cost allocations are made in such cases is to determine the reasonableness of the charges made or to obtain a basis for determining what charges should be made. Regardless of the allocation of cost and the resulting charges for services, the total annual revenue to be received by the utility would depend only on the total annual cost of rendering service, provided, of course, that such cost is less than the cost of an alternative supply.

The justification of a multiple-purpose project, from an engineering point of view, depends only on the total annual cost of the services from the project being less than the minimum total annual justifiable cost (that is, cost which is less than the annual benefits) of obtaining the same services otherwise. The total annual revenue, as for a single-purpose project, should depend only on the total annual cost of rendering the services, provided it is not greater than the minimum annual cost of obtaining the same services otherwise. Except for this limitation, the total annual revenue should be independent of both the cost of obtaining the same services otherwise and of any cost allocation that may be made.

---

[12] Efficiency Engr., Pennsylvania Water & Power Co., Baltimore, Md.

[13] The late Pres., Safe Harbor Water Power Corp., Baltimore, Md. Mr. Allner died on July 18, 1942.

The only reason for making a cost allocation is to obtain a basis for the rates and charges for various services that will result in a total annual revenue as nearly equal to the total annual cost as possible. If it is the public policy not to collect revenue for various services of government-owned, multiple-purpose projects and to make only nominal charges for others, the resulting deficiencies will have to be subsidized from general taxes. The amount of such subsidies should be determined directly as a matter of public policy and not indirectly (as is most often done), by means of a cost allocation.

The questions as to whether or not a project should be subsidized and the extent of the subsidy are political questions rather than problems of engineering economics. The application of engineering economics to a project as a whole ends when it has been determined whether or not the project is economically justified; and the political decisions with respect to such projects, rather than the engineering and economic facts, should be based on the declared public policy. The answer to the question as to what extent, if any, it is the public policy to subsidize such projects depends in turn on the public's knowing the true annual cost, including the controversial question as to the "cost of money."

The money invested belongs to the public regardless of whether the project is "privately" or "publicly" owned; in the one case the money invested belongs to specific individuals or groups and in the other to the public generally. The economics of a project do not change merely because it is sponsored by the government. An important difference between the financing of a project by the government or by a private company is that the government, particularly the federal government, has much greater resources. An apparent difference arises from the fact that, because of tax regulations and the safety to investors in government securities provided by its taxing powers, the government is usually able to borrow at a lower rate than a private enterprise. This does not necessarily mean, as is often assumed, that the cost of money to the government for any particular purpose is less than that to a responsible private company for the same kind of undertaking. This is true even though the government, if it so desires, may finance a project entirely with borrowed money, whereas private companies must usually provide substantial portions of equity money in addition to that borrowed.

It is frequently forgotten that the government's "equity" is provided by the taxpayers who must bear the burden of all losses suffered on account of investments in such projects. It is difficult to understand logic that assumes the public places less value on its money and is willing for the money to earn a lower return simply because it was invested through the government instead of a private company. The answer is that the money used in the same project is worth the same, regardless of who made the investment, assuming equally capable management in each case, since the risks would then be the same. Further, it is not believed that the interest rate paid by the government alone tells the entire story as to the cost of the public's money used by the government for such purposes. The present situation as to taxes makes this point more clear. The unevaluated portion of the cost of the public's money used by the government is the necessary sacrifice of the public to make money available to the government for its various activities. This fact has always existed and is only made more clear by present conditions. For example, if one assumes no public debt (as a result of a pay-as-you-go program), the government would pay no interest on the money expended by it for any purpose. Should one then assume zero cost for the money spent by the government for such projects? The fact of the matter is that there is no magic in government ownership, and the cost of money to it is the average return demanded by the public itself for investments in reasonably safe private undertakings. Such a basis for determination serves as an indirect, but nevertheless reliable, method of evaluating previously neglected elements of cost of money to the government. The economic justification of the project and its true annual total cost should both be computed on the foregoing basis for determining the cost of money. The total annual revenue should be equal to this total annual cost to make the project self-supporting. However, it may be the public policy that no revenue be received from some of the purposes of the project, with only nominal revenue from others, and normal revenue from the remaining purposes.

To illustrate, assume a multiple-purpose project built for flood control, navigation, power and energy production, and recreation; and assume that it is the public policy that no direct charges be made for flood-protection benefits, that only nominal charges be made for use of the recreation facilities, and that normal charges be made for navigation and power and energy. The total annual cost of the project is $3,700,000, of which $300,000 is the annual cost incurred specifically for flood control, $400,000 specifically for navigation, $1,500,000 specifically for power and energy production, $100,000 specifically for recreation, and the remainder of $1,400,000 for joint facilities. The nominal charges made for the use of the recreation facilities result in an annual revenue of $20,000. The problem is to determine the rates and charges that should be made for the use of the navigation facilities and for power and energy. It is believed, as stated previously, that there is no correct engineering solution to this problem, in the scientific sense, and that the determination of the cost allocation to the various purposes is necessarily arbitrary, regardless of how it may be derived.

The total annual revenue desired is likewise a matter of public policy, which one may assume would be either (1) as large as possible, (2) approximately equal to the total annual cost of the project even though flood control is to be wholly, and recreation largely, subsidized, (3) equal to some specified amount, (4) less than the total annual cost of the project by some specified amount, or (5) equal to some specified percentage of the total annual cost of the project.

It is believed that the underlying principle of the vendibility theory of cost allocation (namely, that services and commodities jointly produced are mutual by-products of each other and that the actual total annual revenue should be as nearly as possible equal to the desired total annual revenue) is the most logical basis for arriving at an equitable, but admittedly arbitrary, basis for allocating the cost of a government-owned, multiple-purpose project to its various purposes. The total revenue received on account of any of the purposes of the project is immaterial, so long as it is not greater than that required to defray the annual cost for the most economical means of obtaining the same services otherwise.

The charges for each of the services should be equal to or less than the smaller of (1) the economic rate (that is, the rate that would produce the maximum net income), and (2) the rate required to be paid for the most economical available means of obtaining the same services otherwise.

If the total annual revenue resulting from the predetermined nominal rates for certain services and those determined in the foregoing manner for the other services (which may be called either separately or in total the unadjusted revenue) is greater than the total desired for the project (as determined by public policy) the rates should be further reduced so that the desired over-all results will be obtained. Such an excess of revenue may result from various combinations of different amounts of earnings on account of the various purposes of the project. Whatever the combination is that causes this excess, it is suggested that the reduction be based on comparisons of the unadjusted annual revenue with the annual cost of the specific facilities for each of the purposes of the project, and of the total unadjusted annual revenue with the total revenue desired.

The simplest case results when the excess, if any, of unadjusted total annual revenue over the desired total annual revenue is derived from only one purpose of the project. This will be the case when there is only one purpose for which the unadjusted annual revenue exceeds the annual cost of specific facilities and this excess is greater than the amount the unadjusted total annual revenue exceeds the desired total annual revenue. It would appear illogical, under such circumstances, to further reduce the annual revenues for those purposes for which the unadjusted annual revenues fail to cover the annual cost of specific facilities; and consequently, such reduction should all be applied to the one purpose for which the unadjusted annual revenue exceeds the annual cost of specific facilities. However, in the event (even though there is only one purpose for which the unadjusted annual revenue exceeds the annual cost of specific facilities for that purpose) that the excess of the unadjusted total annual revenue over the desired total annual revenue is greater than such excess for that one purpose, the situation becomes rather complex and more complicated treatment of the problem, as discussed later, is necessary.

If there are several purposes of the project for which the unadjusted annual revenues exceed the annual cost of specific facilities, there are, as brought out in the preceding special case, two possible conditions, one of which is relatively simple and the other more complex. The simple condition results when the excess of the unadjusted total annual revenue over the total annual revenue desired is less than the total of the excesses of the unadjusted annual revenues over the annual cost of specific facilities for those purposes of the project for which there are such excesses. The reduction to be made for the simple case should be on a proportional basis to those purposes of the project having such excess revenues.

To illustrate, assume for the example given previously that the unadjusted annual revenue is $1,500,000 for navigation and $2,800,000 for power and energy, which for navigation is $1,100,000 and for power and energy $1,300,000 in excess of the annual cost of the specific facilities for those purposes. These unadjusted annual revenues, together with those from recreation, give \$4,320,000 as the total annual revenue from the project. If the desired annual revenue is \$3,000,000, the total reduction for navigation and power and energy would be \$1,320,000, whereas the sum of the excess revenues for these purposes is \$2,400,000. The reduction to be applied to navigation then would be $\frac{11}{24} \times \$1{,}320{,}000$, or \$605,000, and to power and energy $\frac{13}{24} \times \$1{,}320{,}000$, or \$715,000. The resulting adjusted revenue for navigation would be \$895,000, and for power and energy \$2,085,000.

The more complex situations result when the desired total annual revenue of the project is so low, in comparison with the unadjusted total annual revenue, that the necessary reduction is greater than the total excess of unadjusted revenue over the annual cost of specific facilities for those purposes of the project for which such excess revenues exist. (The case in which there was no purpose of the project for which the unadjusted annual revenue exceeded the annual cost of specific facilities would also be included here.) In order to make the desired reduction in total revenue for such cases, not only revenues from otherwise "profitable" purposes of the project, if any, must be reduced below the annual costs of specific facilities for these purposes, but revenues from the "unprofitable" purposes of the project may also be further reduced.

The solution suggested herein involves the finding of a ratio, less than unity, which when applied to the specific cost of facilities for any purpose will give the adjusted revenue for that purpose, provided the revenue is reduced thereby (that is, the revenue for any purpose is to be reduced or must remain unchanged). The ratio to be determined must also satisfy the condition that adjusted revenues (including those that remain unchanged) must total to the desired revenue from the project.

To illustrate, assume the same data for the project as previously used, except that the total desired annual revenue is only \$1,000,000 (that is, the subsidy has been increased \$2,000,000 as compared with the previous example). The total annual cost of specific facilities, excluding those for flood control, is \$2,000,000. This total multiplied by 50%, the ratio of the desired annual revenue to the total annual cost of specific facilities, would give the desired \$1,000,000 total revenue. It is immediately apparent, however, that the 50% ratio applied to the cost of facilities for recreation (\$100,000) would give a revenue in excess of the \$20,000 predetermined for this purpose. Consequently, the computation of the ratio must be adjusted by excluding the annual cost of recreation facilities and recreation revenue. The total annual cost of specific facilities for navigation and power and energy is \$1,900,000, and the desired revenue, after deducting \$20,000 for recreation, \$980,000. The ratio of desired revenue to cost is then 0.516. The adjusted revenue for navigation would then be \$400,000 × 0.516, or \$206,400, and for power and energy \$1,500,000 × 0.516, or \$773,600. The total adjusted revenue, including \$20,000 from recreation, is the desired \$1,000,000.

These two methods of distributing the excess of the unadjusted total annual revenue over the total annual revenue desired among the revenues from the various purposes of a multiple-purpose project have a common point at which their results necessarily agree. At this point the desired reduction in total revenue is just equal to the sum of the excesses of unadjusted annual revenues over the annual cost of specific facilities for those purposes for which excesses exist.

This suggested basis for determining the charges to be made for the various services rendered by multiple-purpose projects is not, in a strict sense, a basis for allocating cost. It is merely a basis for the determination of the charges to be made for these various services in accordance with a declared public policy, not only as to what purposes of the project are to be subsidized, but also as to what extent the project as a whole is to be subsidized. The procedure used by the author (assuming that the rates for the various services are based on the cost allocation) results in a subsidy for the project as a whole which varies as the cost allocated to the various purposes varies. The subsidy increases as the cost allocated to the no-revenue and small-revenue producing purposes of the project increases. On the other hand, the application of the foregoing suggested basis for determining the charges to be made for the various services of the project assures the return that is desired from the project as a whole in accordance with public policy, and the public policy as to what purposes shall be subsidized as no-revenue and small-revenue producing. At the same time it makes available the various services, for which normal charges are to be made, at the same or less cost than the minimum for which they could be obtained otherwise. Thus, the beneficiaries of such services have no basis for complaint, since they are not hurt, whereas the interests of the general public are protected to a definite predetermined extent.

THEODORE B. PARKER,[14] M. AM. SOC. C. E.—The discussions have elicited much additional information which undoubtedly will be of value to those interested in the subject. It is particularly gratifying to note that the discussers seem to be in substantial agreement with the methods used by the Tennessee Valley Authority.

Colonel Elliott agrees generally with the methods used in determining the costs to be allocated to the various purposes of a multiple-purpose project, but questions the use of a cost allocation, in particular with reference to the so-called power "yardstick." If it were conceded, for the purpose of the argument, that the costs of private and public enterprises were different, or, for that matter, that the costs of construction or types of structures required in different parts of the country were different, it would seem to the writer that adjustments for these differences could be made readily. Without a cost allocation to which such adjustments could be applied, there would be no base from which to begin in making any comparison. It should also be kept in mind that the capital cost of the generating stations is only a comparatively small part of the cost of power and that transmission, distribution, and marketing costs are not subject to allocation. It follows that even if the cost of generation for a public enterprise were 70% of the cost of generation of a private enterprise, the actual costs of power at market would be more nearly equal.

---

[14] Chf. Engr., TVA, Knoxville, Tenn.

Mr. Chandler presents, in some detail, interesting variations of the alternative-justifiable-expenditure method which will greatly assist the uninitiated in a better understanding of the problem. However, it appears to the writer that, in the use of the so-called "three-circle" method, simplicity of the alternative-justifiable-expenditure method is sacrificed without much, if any, gain in accuracy since a considerably larger number of estimates of cost are required.

Professor Grant raises an interesting and pertinent point by requesting more information on the effect of different plans of operation on the cost allocations. In accordance with the TVA Act, flood control and navigation are the primary purposes, and power is the by-product of the development of the Tennessee River and its tributaries. The Act is clear and specific, the various developments are planned and operated accordingly, and in normal times, therefore, there cannot be any choice as to plan of operation; the cost allocations are made to conform with this plan. However, the Authority has in operation (among others) the Cherokee Dam on the Holston River and the Nottely and Chatuge developments in the upper Hiwassee drainage basin, which, by special appropriation of the Congress, were authorized to alleviate a threatened power shortage in the region. During the hearings before the Congressional committees on the bill authorizing the construction of these projects, it was fully explained that these dams were to be operated temporarily for the primary purpose of maximum power production, and that at the conclusion of the war the operation of the dams would revert to the normal multiple-purpose operating plan.

To conform to the realities of this situation, the writer is recommending that the Authority submit two cost allocations for approval by the President of the United States—one to apply for the duration of the war and charging the entire cost of the additional developments to power, the other to go into effect after the Congress has declared the war emergency to be ended and giving effect to the planned multiple-purpose operation of the projects.

It is interesting to note that the methods used are sufficiently flexible to allow for this difference in operation as well as sufficiently accurate so that the difference in operation does not disappear in the process of allocation.

Mr. Woodward's discussion is a worth-while addition to the conception of allocations, and offers an alternative allocation principally involving the cost of Hiwassee Dam and affecting only the allocated costs of navigation and flood control.

Mr. Arledge summarizes clearly and concisely the various steps taken by the Congress with regard to the financing of the Boulder Canyon project. This discussion contains much valuable information which the individual engineer could only find after considerable research, if at all. The remarks of Mr. Watchorn and the late Mr. Allner do not appear to be particularly pertinent to the solution of the problem of cost allocation of the TVA projects as directed by the Congress. However, their discussion presents a thoughtful opinion on the general subject of allocations.

In conclusion, the writer wishes to express his sincere appreciation to all the discussers.

BENDING MOMENTS IN THE WALLS OF RECTANGULAR TANKS

BY DANA YOUNG,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. I. K. SILVERMAN, AND DANA YOUNG.

SYNOPSIS

An attempt is made herein to obtain a theoretical solution for the deflection and moments in the vertical side walls of a rectangular tank which is open at the top. More precisely, a formal analysis is made of a rectangular plate that is entirely free or unsupported at the top, perfectly fixed along the sides and bottom and subjected to a transverse hydrostatic loading. In certain cases, the walls of a rectangular tank, as shown in Fig. 1, may be considered to act as plate with these idealized edge conditions, and it is only in such cases that this analysis applies. For a tank that is square in plan and with a heavy base, perfected fixity at the sides and bottom would be closely approached. If one horizontal dimension is much greater than the other, the assumed edge conditions would not prevail. This analysis may be said to furnish the solution for an idealized case and the designer must use judgment in applying the results to a particular problem.

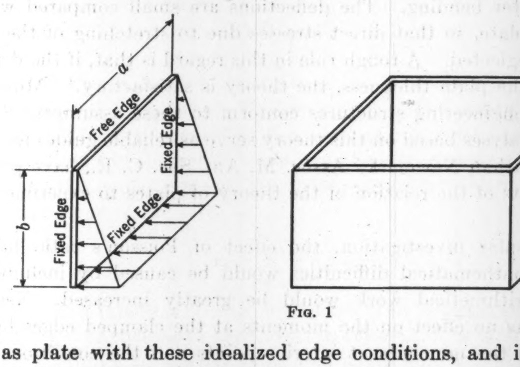

FIG. 1

NOTE.—Published in November, 1941, *Proceedings*.

[1] Prof., Applied Mechanics, The Univ. of Texas, Austin, Tex.

There are other possible applications besides that of a tank wall. The vertical slab in a counterfort retaining wall may be considered as such a plate providing the bottom edge is designed for fixity. The flat slab of a buttress dam is in the same category.

The analysis given herein is based on the so-called ordinary theory of bending of thin plates. According to this theory, the load on the plate and the shape of the deflected surface of the plate are related by a partial differential equation. An analysis of the problem involves finding a solution of the differential equation which also satisfies the specified edge conditions for the plate. After this deflection function is found, the bending moments may be determined from the second derivatives of the function. The derivation of the differential equation and the expressions for moments, shears, and reactions are given by various writers such as S. Timoshenko[2] and A. Nadai.[3]

INTRODUCTION

The theory of the bending of plates used in this paper is based upon several assumptions that must be considered in interpreting the results of the analysis. The principal assumptions may be noted briefly. The plate is assumed to be homogeneous, isotropic, and of constant thickness. The thickness of the plate is small compared with its lateral dimensions, so that the effect of shearing stresses on the deflection may be neglected. A line that is normal to the plane of the plate before bending remains straight and normal to the deflected middle surface after bending. The deflections are small compared with the thickness of the plate, so that direct stresses due to stretching of the middle surface may be neglected. A rough rule in this regard is that, if the deflection is less than half the plate thickness, the theory is satisfactory.[4] Most plates or slabs used in engineering structures conform to these assumptions closely enough so that analyses based on this theory serve as reliable guides for design. A. Nadai[3] and Nathan Newmark,[5] Assoc. M. Am. Soc. C. E., have presented detailed statements of the relation of the theory of plates to experiments and design.

In this particular investigation, the effect of Poisson's ratio has been neglected. No mathematical difficulties would be caused by including this item, but the arithmetical work would be greatly increased. Neglecting Poisson's ratio has no effect on the moments at the clamped edges but does affect, somewhat, the moments at interior points and the conditions at the free edge. Corrections to the interior moments for any given value of Poisson's ratio can be made.[2,3]

NOTATION

The letter symbols in this paper are defined where they first appear and are assembled for reference in the Appendix.

GENERAL PROCEDURE

This problem requires the solution of the differential equation

$$\frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^4 w}{\partial x^2\,\partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{q}{D} \qquad (1)$$

with the boundary conditions (assuming Poisson's ratio as zero):

At $x = 0.5\,a$,

$$w = 0 \quad \text{and} \quad \frac{\partial w}{\partial x} = 0 \qquad (2a)$$

At $y = b$,

$$w = 0 \quad \text{and} \quad \frac{\partial w}{\partial y} = 0 \qquad (2b)$$

At $y = 0$,

$$\frac{\partial^2 w}{\partial y^2} = 0 \quad \text{and} \quad \frac{\partial^3 w}{\partial y^3} + 2\frac{\partial^3 w}{\partial x^2\,\partial y} = 0 \qquad (2c)$$

In Eqs. 1 and 2: w is the deflection of the plate at any point; q is the intensity of a distributed lateral load; x and y are the rectangular coordinates in the plane of the middle surface of the plate; a and b are the dimensions of the plate in the x and y directions, respectively; and D, the flexural rigidity of the plate, is equal to

$$D = \frac{E\,h^3}{12\,(1 - \mu^2)} \qquad (3)$$

in which: E is the modulus of elasticity of the plate material; h is the thickness of the plate; and μ represents Poisson's ratio. The difficulty in solving this problem arises from the fact that there is no known procedure for solving the differential equation subject to these boundary conditions. The most general solution for rectangular plates is the one due to Levy[6] which uses for the deflection an expression of the form

$$w = \sum_{m=1}^{\infty} X_m \sin\frac{m\,\pi\,y}{b} \qquad (4)$$

in which X_m is a function of x alone; and m is an integer (which has the value 1, 2, 3 ··· to ∞ in successive terms of the series). The solution requires that the plate be simply supported along two edges and any boundary conditions may be prescribed at the other two edges. Therefore, it cannot be applied directly to the problem at hand. However, it is possible (in a manner somewhat analogous to that proposed by S. Timoshenko[7] for plates clamped at all four edges) to solve the problem by a proper combination of several loadings, each of which is of the form of Eq. 4.

[6] "Die elastischen Platten," by A. Nadai, Julius Springer, Berlin, 1925, p. 120.

[7] "Bending of Rectangular Plates with Clamped Edges," by S. Timoshenko, *Proceedings*, Fifth International Cong. for Applied Mechanics, Cambridge, Mass., 1938, p. 40.

For this purpose, the four cases shown in Fig. 2 are taken, each of which is simply supported along one pair of edges. Fig. 2(*a*) carries an hydrostatic loading, is simply supported at $x = \pm 0.5\,a$, fixed at $y = b$, and has a free edge at $y = 0$. Fig. 2(*b*) has no lateral load but is bent by arbitrary edge moments

$$(M_x)_{x=\pm\frac{a}{2}} = \sum_{m=1}^{\infty} F_m \sin\frac{m\,\pi\,y}{b} \ldots\ldots\ldots\ldots\ldots\ldots (5a)$$

FIG. 2

the distribution of which along the edges is taken in the form of a trigonometric series with undetermined coefficients F_m. Fig. 2(*c*) is bent by edge moments

$$(M_y)_{y=b} = \sum_{k=1,3,5,\cdots} E_k \cos\frac{k\,\pi\,x}{a} \ldots\ldots\ldots\ldots\ldots (5b)$$

and Fig. 2(*d*) is bent by arbitrary edge reactions at $y = 0$ of the form

$$(R_y)_{y=0} = \sum_{k=1,3,5\cdots} R_k \cos\frac{k\,\pi\,x}{a} \ldots\ldots\ldots\ldots\ldots\ldots (5c)$$

In Eqs. 5, M_x and M_y are the bending moments per unit length of plate on sections perpendicular to the x and y axes, respectively; R_x and R_y are the reactions per unit length of plate along edges perpendicular to the x and y axes, respectively; m and k are integers, with values as indicated on the summation signs; and F_m, E_k, R_k, etc., are constants. The boundary conditions at the edges of these plates are as shown in Fig. 2. The deflection surface for each of these plates may be obtained by Levy's method and then these four solutions combined in such a manner that Eq. 1 and the boundary conditions, Eqs. 2, are satisfied. This leads to a set of simultaneous algebraic equations from which the values of the coefficients F_m, E_k, and R_k may be calculated.

The method of obtaining the deflection equation for the four cases will be illustrated by considering Fig. 2(*d*). Results for the other cases will then be given without proof since the same procedure applies.

DEFLECTION EQUATION FOR FIG. 2(*d*)

Denote the deflection in this case by w_4. Since there is no distributed lateral load on the plate, the differential equation (Eq. 1) reduces to

$$\frac{\partial^4 w_4}{\partial x^4} + 2\frac{\partial^4 w_4}{\partial x^2\,\partial y^2} + \frac{\partial^4 w_4}{\partial y^4} = 0 \qquad \text{(6)}$$

The boundary conditions are:

At $x = \pm 0.5\,a$,

$$w_4 = 0 \quad \text{and} \quad \frac{\partial^2 w_4}{\partial x^2} = 0 \qquad \text{(7a)}$$

At $y = b$,

$$w_4 = 0 \quad \text{and} \quad \frac{\partial w_4}{\partial y} = 0 \qquad \text{(7b)}$$

At $y = 0$,

$$\frac{\partial^2 w_4}{\partial x^2} = 0 \quad \text{and} \quad -D\left(\frac{\partial^3 w_4}{\partial y^3} + 2\frac{\partial^3 w_4}{\partial x^2\,\partial y}\right) = \sum_{k=1,3,5\cdots} R_k \cos\frac{k\,\pi\,x}{a} \qquad \text{(7c)}$$

Take the deflection function in the form

$$w_4 = \sum_{k=1,3,5\cdots} Y_k \cos\frac{k\,\pi\,x}{a} \qquad \text{(8)}$$

in which Y_k is a function of y alone. Substituting Eq. 8 in Eq. 6, the function Y_k is found to be

$$\begin{aligned} Y_k = {} & G_k \cosh\frac{k\,\pi\,y}{a} + G'_k\,\frac{k\,\pi\,y}{a}\cosh\frac{k\,\pi\,y}{a} \\ & + G''_k \sinh\frac{k\,\pi\,y}{a} + G'''_k\,\frac{k\,\pi\,y}{a}\sinh\frac{k\,\pi\,y}{a} \end{aligned} \qquad \text{(9)}$$

From the boundary conditions Eqs. 7*b* and 7*c*, the four constants in Eq. 9 are found to be

$$\left.\begin{aligned} G_k &= \frac{2\,a^3\,R_k}{k^3\,\pi^3\,D\,K_k}\left[\tanh\alpha_k - \alpha_k\,(1 - \tanh^2\alpha_k)\right] \\ G'_k &= \frac{a^3\,R_k}{k^3\,\pi^3\,D\,K_k}\,(2 - \tanh^2\alpha_k) \\ G''_k &= G'_k + \frac{a^3\,R_k}{k^3\,\pi^3\,D} \\ G'''_k &= -\,0.5\,G_k \end{aligned}\right\} \qquad \text{(10)}$$

in which

$$K_k = \tanh^2\alpha_k - \alpha^2_k\,(1 - \tanh^2\alpha_k) - 4 \qquad \text{(11)}$$

α_k being equal to $\dfrac{k\,\pi\,b}{a}$.

Deflection Equation for Figs. 2(*a*), 2(*b*), and 2(*c*)

The deflection equations for the other cases are derived in a similar manner; thus, for Fig. 2(*a*):

$$w_1 = \frac{\gamma a^4}{\pi^5 D} \sum_{k=1,3,5\cdots} \frac{(-1)^{\frac{k-1}{2}}}{k^5} \left(4\,y + A_k \cosh\frac{k\,\pi\,y}{a} + A'_k \frac{k\,\pi\,y}{a} \cosh\frac{k\,\pi\,y}{a} + A''_k \sinh\frac{k\,\pi\,y}{a} + A'''_k \frac{k\,\pi\,y}{a} \sinh\frac{k\,\pi\,y}{a}\right) \cos\frac{k\,\pi\,x}{a} \qquad (12)$$

in which: $A_k = \frac{a\,\delta_k}{k\,\pi\,K_k}$; $A'_k = \frac{a\,\omega_k}{k\,\pi\,K_k}$; $A''_k = A'_k - \frac{8\,a}{k\,\pi}$; $A'''_k = -\,0.5\,A_k$; and

$$\delta_k = 16\,\alpha_k\,(1 - \tanh^2\alpha_k) - 16\tanh\alpha_k + \frac{8}{\cosh\alpha_k}(\alpha_k - \tanh\alpha_k + \alpha^2_k \tanh\alpha_k) \qquad (13a)$$

$$\omega_k = 8\tanh^2\alpha_k - 16 + \frac{1}{\cosh\alpha_k}(8 + 4\,\alpha^2_k - 8\,\alpha_k\tanh\alpha_k) \qquad (13b)$$

and K_k is defined by Eq. 11.

Similarly, the deflection equation for Fig. 2(*b*) is:

$$w_2 = \frac{b^2}{2\,\pi^2 D} \sum_{m=1}^{\infty} \frac{F_m}{m^2\cosh\beta_m} \times \left(\beta_m \tanh\beta_m \cosh\frac{m\,\pi\,x}{b} - \frac{m\,\pi\,x}{b}\sinh\frac{m\,\pi\,x}{b}\right) \sin\frac{m\,\pi\,y}{b} \qquad (14a)$$

and the deflection equation for Fig. 2(*c*) is:

$$w_3 = \frac{a^2}{\pi^2 D} \sum_{k=1,3,5\cdots} \frac{E_k}{k^2\cosh\alpha_k} \left(B_k \cosh\frac{k\,\pi\,y}{a} + B'_k \frac{k\,\pi\,y}{a}\cosh\frac{k\,\pi\,y}{a} + B''_k \sinh\frac{k\,\pi\,y}{a} + B'''_k \frac{k\,\pi\,y}{a}\sinh\frac{k\,\pi\,y}{a}\right) \cos\frac{k\,\pi\,x}{a} \qquad (14b)$$

In Eqs. 14: $\beta_m = \frac{m\,\pi\,a}{2\,b}$; $\alpha_k = \frac{k\,\pi\,b}{a}$; and—

$$\left.\begin{aligned} B_k &= \frac{\alpha_k + \tanh\alpha_k}{3\tanh\alpha_k + \alpha_k\,(1 - \tanh^2\alpha_k)} \\ B'_k &= \frac{0.5\,\alpha_k\tanh\alpha_k - 1}{3\tanh\alpha_k + \alpha_k\,(1 - \tanh^2\alpha_k)} \\ B''_k &= B'_k \\ B'''_k &= -\,0.5\,B_k \end{aligned}\right\} \qquad (15)$$

EQUATIONS FOR DETERMINING F_m, E_k, AND R_k

The solution for the given problems is to be obtained by superposition of the solutions for the four cases in Fig. 2, by taking

$$w = w_1 + w_2 + w_3 + w_4 \quad \text{(16)}$$

Coefficients F_m, E_k, and R_k are to be so determined that the boundary conditions in Eq. 2 will be satisfied. Thus, for the condition that the slope is zero at $y = b$,

$$\left(\frac{\partial w_2}{\partial y}\right)_{y=b} + \left(\frac{\partial w_3}{\partial y}\right)_{y=b} = 0 \quad \text{(17)}$$

Differentiating, Eq. 14*a* gives

$$\left(\frac{\partial w_2}{\partial y}\right)_{y=b} = \frac{b}{2\,\pi\,D} \sum_{m=1}^{\infty} \frac{(-1)^m F_m}{m \cosh \beta_m} \times \left(\beta_m \tanh \beta_m \cosh \frac{m\,\pi\,x}{b} - \frac{m\,\pi\,x}{b} \sinh \frac{m\,\pi\,x}{b}\right) \quad \text{(18a)}$$

and from Eq. 14*b*

$$\left(\frac{\partial w_3}{\partial y}\right)_{y=b} = \frac{a}{2\,\pi\,D} \sum_{k=1,3,5\cdots} \frac{E_k}{k} \frac{(1 + \alpha^2_k)(\tanh^2 \alpha_k - 1) - 3}{3 \tanh \alpha_k + \alpha_k (1 - \tanh^2 \alpha_k)} \cos \frac{k\,\pi\,x}{a} \quad \text{(18b)}$$

Before substituting the two slope expressions in Eq. 17, it is expedient to expand the expression inside the brackets in Eq. 18*a* in a Fourier cosine series. Doing this, and then substituting in Eq. 17 the following equation is obtained connecting the coefficients E_k and F_m:

$$E_k \frac{(1 + \alpha^2_k)(1 - \tanh^2 \alpha_k) + 3}{3 \tanh \alpha_k + \alpha_k (1 - \tanh^2 \alpha_k)} = \frac{8\,(-1)^{\frac{k-1}{2}}\,k^2\,b^3}{\pi\,a^3} \sum_{m=1}^{\infty} \frac{(-1)^m\,m\,F_m}{\left(m^2 + \dfrac{k^2\,b^2}{a^2}\right)^2} \quad \text{(19)}$$

There will be one equation of the form of Eq. 19 for each value of $k = 1, 3, 5, \cdots$, and each of these will have an infinite number of terms on the right-hand side.

In a similar manner, from the condition that the reaction

$$R_y = -D\left(\frac{\partial^3 w}{\partial y^3} + 2\,\frac{\partial^3 w}{\partial x^2\,\partial y}\right) \quad \text{(20a)}$$

at $y = 0$ must be zero, the following system of equations is obtained:

$$R_k = -\frac{4\,(-1)^{\frac{k-1}{2}}\,k\,b}{a^2} \sum_{m=1}^{\infty} m\,F_m \frac{m^2 + \dfrac{2\,k^2\,b^2}{a^2}}{\left(m^2 + \dfrac{k^2\,b^2}{a^2}\right)^2} \quad \text{(20b)}$$

From the condition that the slope at $x = 0.5\,a$ must be zero:

$$
\begin{aligned}
&F_m\left(\tanh\beta_m + \frac{\beta_m}{\cosh^2\beta_m}\right) + \frac{4\,m^2 a^3}{\pi\,b^3}\sum_{k=1,3,5\cdots}\frac{k\,(-1)^{\frac{k-1}{2}}\,E_k}{\left(k^2 + \frac{m^2 a^2}{b^2}\right)^2} \\
&\times\left\{\frac{(\alpha_k + \tanh\alpha_k)\left(2 + \frac{m^2 a^2}{k^2 b^2}\right)}{[3\tanh\alpha_k + \alpha_k\,(1 - \tanh^2\alpha_k)]\cosh\alpha_k} - (-1)^m\right\} \\
&+ \frac{8\,m^2 a^4}{\pi^2 b^3}\sum_{k=1,3,5\cdots}\frac{(-1)^{\frac{k-1}{2}}\,R_k}{K_k\left(k^2 + \frac{m^2 a^2}{b^2}\right)^2}\Bigg\{[\tanh\alpha_k - \alpha_k\,(1 - \tanh^2\alpha_k)] \\
&\times\left(2 + \frac{m^2 a^2}{k^2 b^2}\right) + (-1)^m\frac{\alpha_k + \tanh\alpha_k}{\cosh\alpha_k}\Bigg\} = -\frac{4\,\gamma\,a^4}{\pi^4 b}\sum_{k=1,3,5\cdots}\frac{1}{k^3} \\
&\times\Bigg\{-\frac{(-1)^m\,4\,k\,\frac{b}{a}}{k^2 + \frac{m^2 a^2}{b^2}} + \frac{\frac{m^2 a^2}{\pi\,b^2}}{\left(k^2 + \frac{m^2 a^2}{b^2}\right)^2 K_k}\Bigg[\delta_k\left(2 + \frac{m^2 a^2}{k^2 b^2}\right) \\
&\qquad + (-1)^m\cosh\alpha_k\,(-\,\delta_k + 2\,\omega_k\tanh\alpha_k)\Bigg]\Bigg\} \qquad\qquad (21)
\end{aligned}
$$

Eqs. 19, 20*b*, and 21 provide the necessary relations for determining F_m, E_k, and R_k. Each one defines an infinite system of equations with an infinite number of terms. To solve these numerically, it is necessary to assume that the series converge and to neglect all terms higher than a given order. The result is a finite system of simultaneous equations that may be solved to obtain values for the coefficients. This completes the solution of the differential Eq. 1 for the specified boundary conditions. The moments at any point may then be determined from the known relations of the plate theory. For example, the moment per unit length of plate on sections perpendicular to the x-axis is given by

$$
M_x = -\,D\frac{\partial^2 w}{\partial x^2} = -\,D\left(\frac{\partial^2 w_1}{\partial x^2} + \frac{\partial^2 w_2}{\partial x^2} + \frac{\partial^2 w_3}{\partial x^2} + \frac{\partial^2 w_4}{\partial x^2}\right) \qquad (22)
$$

assuming that Poisson's ratio is zero.

NUMERICAL EXAMPLE

For an example, assume a tank with square sides for which $a = b$; and in each of Eqs. 19, 20*b*, and 21 take only the first four terms of each series. Then in Eq. 19, using $m = 1, 2, 3$, and 4, and taking $k = 1, 3, 5$, and 7, successively, the numerical values of the constants may be computed to obtain the four equations:

$$
\left.
\begin{aligned}
1.0228\,E_1 &= -\,0.6366\,F_1 + 0.2037\,F_2 - 0.0764\,F_3 + 0.0352\,F_4 \\
1.0000\,E_3 &= 0.2292\,F_1 - 0.2712\,F_2 + 0.2122\,F_3 - 0.1467\,F_4 \\
1.0000\,E_5 &= -\,0.0942\,F_1 + 0.1514\,F_2 - 0.1652\,F_3 + 0.1515\,F_4 \\
1.0000\,E_7 &= 0.0499\,F_1 - 0.0888\,F_2 + 0.1113\,F_3 - 0.1181\,F_4
\end{aligned}
\right\} \qquad (23a)
$$

Calculation of the constants in Eq. 20*b* gives the system:

$$\left.\begin{aligned}
a R_1 &= -\,3.0000\,F_1 - 1.9200\,F_2 - 1.3200\,F_3 - 0.9965\,F_4 \\
a R_3 &= 2.2800\,F_1 + 3.1243\,F_2 + 3.0000\,F_3 + 2.6112\,F_4 \\
a R_5 &= -\,1.5089\,F_1 - 2.5683\,F_2 - 3.0623\,F_3 - 3.1410\,F_4 \\
a R_7 &= 1.1088\,F_1 + 2.0335\,F_2 + 2.6718\,F_3 + 3.0220\,F_4
\end{aligned}\right\} \ldots (23b)$$

Finally, from Eq. 21, compute the following set of numerical equations:

$$\left.\begin{aligned}
&1.1666\,F_1 + 0.4314\,E_1 - 0.0382\,E_3 + 0.0094\,E_5 \\
&\qquad - 0.0036\,E_7 - 0.1685\,a R_1 + 0.0057\,a R_3 \\
&\qquad\qquad - 0.0008\,a R_5 + 0.0002\,a R_7 = -\,0.04694\,\gamma a^3 \\
&1.0197\,F_2 - 0.0589\,E_1 + 0.0903\,E_3 - 0.0303\,E_5 \\
&\qquad + 0.0127\,E_7 - 0.2608\,a R_1 + 0.0156\,a R_3 \\
&\qquad\qquad - 0.0028\,a R_5 + 0.0008\,a R_7 = -\,0.03474\,\gamma a^3 \\
&1.0014\,F_3 + 0.2640\,E_1 - 0.1063\,E_3 + 0.0496\,E_5 \\
&\qquad - 0.0238\,E_7 - 0.2450\,a R_1 + 0.0225\,a R_3 \\
&\qquad\qquad - 0.0050\,a R_5 + 0.0016\,a R_7 = -\,0.02586\,\gamma a^3 \\
&1.0001\,F_4 + 0.0799\,E_1 + 0.0976\,E_3 - 0.0606\,E_5 \\
&\qquad + 0.0338\,E_7 - 0.2603\,a R_1 + 0.0261\,a R_3 \\
&\qquad\qquad - 0.0068\,a R_5 + 0.0024\,a R_7 = -\,0.03485\,\gamma a^3
\end{aligned}\right\} \ldots (23c)$$

There are now 12 unknowns in 12 simultaneous equations. Solving these equations yields the following values for the coefficients:

$$\begin{aligned}
F_1 &= -\,0.0314\,\gamma a^3 & E_1 &= 0.0190\,\gamma a^3 & R_1 &= 0.1076\,\gamma a^2 \\
F_2 &= -\,0.0030\,\gamma a^3 & E_3 &= -\,0.0063\,\gamma a^3 & R_3 &= -\,0.0999\,\gamma a^2 \\
F_3 &= -\,0.0026\,\gamma a^3 & E_5 &= 0.0023\,\gamma a^3 & R_5 &= 0.0765\,\gamma a^2 \\
F_4 &= -\,0.0043\,\gamma a^3 & E_7 &= -\,0.0011\,\gamma a^3 & R_7 &= -\,0.0608\,\gamma a^2
\end{aligned}$$

The bending moments and the deflection at any point may now be computed, the results being shown in Figs. 3 and 4.

The numerical values given are approximate due to the fact that only four terms were taken in each series. However, each of the functions used satisfies the differential equation and gives zero deflection along the sides and bottom of the plate. The inaccuracy arises from the fact that the slope at these edges will not quite be zero, and the top edge will not quite be free, unless an infinite number of terms is used. An insight into the error involved may be

TABLE 1.—Numerical Values[a] for Edge Slopes

obtained by computing the actual slope along the edges for the problem as solved. Results of such a calculation are given in Table 1. From this it is seen that the actual edge slopes remaining are only a few per cent of the corresponding slopes for Fig. 2(a) which has simply supported edges. So it may

be concluded that the values found in this example are sufficiently accurate for design purposes.

To repeat: The ordinary theory of bending of plates, and the results found from it, are valid only if the deflections are small compared to the wall thick-

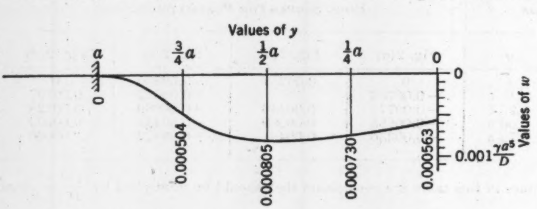

FIG. 4.—DEFLECTION ALONG VERTICAL CENTER LINE

ness. This condition may be readily investigated for any particular design. For example, take a steel water tank with sides 100 in. square. The maximum moment per linear inch is $M = -0.0353\,\gamma\,a^3 = -0.0353 \times 100^3 \times \frac{62.5}{1{,}728}$ $= -1{,}280$ in-lb per in. Assuming an allowable bending stress of 18,000 lb per sq in., $\frac{18{,}000\,h^2}{6} = 1{,}280$; from which $h = 0.654$ in., say $\frac{11}{16}$ in. The maximum deflection is given by $w = 0.000805\,\frac{\gamma\,a^5}{D} = 0.33$ in. using $E = 30{,}000{,}000$ lb per sq in. and $\mu = 0.3$. This gives a ratio of deflection to wall thickness of $\frac{0.33}{0.6875} = 0.48$ which is just about the maximum permissible.

OTHER SOLUTIONS

This same problem has been solved by other investigators using different methods. P. T. Cheng[8] approached the problem by choosing deflection functions containing arbitrary constants which he determined numerically by satisfying the boundary conditions at a finite number of points along the edges. His final values for the moments and deflections check, very closely, the values given herein. Calculations by the method of finite differences have been made by A. Smotrow[9] for the same problem, using a network of 36 squares. The moment values thus obtained are appreciably smaller than those found in this paper. For example, the maximum moment at the base is given by Smotrow as $0.030\,\gamma\,a^3$ as compared to $0.0353\,\gamma\,a^3$ given in Fig. 3. This is to be expected, and it is believed that a closer network of points would have to be taken in the finite difference method to obtain the accuracy of the superposition method used herein. Smotrow also completed the calculations for plates with $\frac{b}{a}$-ratios of 1.5 and 0.67.

MOMENTS FOR PLATES OF OTHER PROPORTIONS

Calculations have been given, in this paper, only for a square plate in which the ratio $\frac{b}{a}$, of the height to the width, is unity. Having the moment values for this case as a standard of comparison, it is possible to approximate moments for plates with other $\frac{b}{a}$-ratios by the consideration of known solutions of plates with the same loading but having other edge conditions.

Consider first the moment M_y at the center of the base of Figs. 5(*a*), 5(*b*), and 5(*c*), all of which carry the same hydrostatic load. Fig. 5(*a*) is the one treated in this paper. Fig. 5(*b*) is similar except that the top edge is simply supported, whereas Fig. 5(*c*) has simply supported side edges and is the same as Fig. 2(*a*). It is clear that the base moment for Fig. 5(*a*) will be greater than for Fig. 5(*b*) and less than for Fig. 5(*c*). For values of $\frac{b}{a}$ greater than unity, the moment for Fig. 5(*a*) will approach that of Fig. 5(*b*), and for values of $\frac{b}{a}$ less than unity, it will approach that of Fig. 5(*c*). Moments for Fig. 5(*b*) with various $\frac{b}{a}$-ratios have been published,[10] and values for Fig. 5(*c*) may be readily calculated from Eq. 12. In Fig. 6 estimated values for Fig. 5(*a*) are indicated by the broken curve drawn through the control point at $\frac{b}{a} = 1$ and approaching the other two curves for other values of $\frac{b}{a}$.

Fig. 5

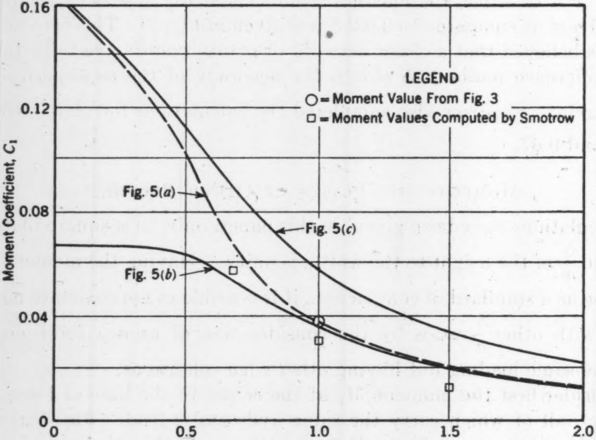

Fig. 6.—Moment at Center of Base: $M_y = -C_1 \gamma b^3$

For the edge moment at the midpoint of each side, it seems reasonable to assume that the value for Fig. 5(*a*) will lie between that for Fig. 5(*b*) and that for Fig. 5(*d*). Values for the case represented by Fig. 5(*d*) are given by Professor Timoshenko.[11] Curves for Figs. 5(*b*) and 5(*d*) are plotted in Fig. 7 from data in the references cited and the assumed curve for Fig. 5(*a*) is indicated by the broken line.

[10] "Analysis of Clamped Rectangular Plates," by D. Young, *Journal of Applied Mechanics*, December, 1940, p. A-139.

It is believed that these moment values are adequate for design purposes. For plates with $\frac{b}{a}$-ratios not too different from unity $\left(\text{say from } \frac{2}{3} \text{ to } \frac{3}{2}\right)$ the distribution of moments along the base may be taken as parabolic and along the sides may be conservatively considered as constant over the middle half and then decreasing uniformly to one half its maximum value at either end.

APPENDIX

NOTATION

The following letter symbols, adopted for use in this paper, conform essentially to Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials, prepared by a Committee of the American Standards Association with Society representation and approved by the Association in 1932.[12] A few obvious conflicts—such as D (standard symbol for diameter) = flexural rigidity and w (standard symbol for uniformly distributed load) = deflection of plate—have been introduced to adapt the notation to common terms found in current literature on flat plate analysis.

A = a constant; with subscripts m or k, the symbols A, B, E, F, G, K, R, δ, and ω are each constants defined where they are used;

δ = (see A);
μ = Poisson's ratio;
ω = (see A).

DISCUSSION

I. K. Silverman,[13] Assoc. M. Am. Soc. C. E.—Even with such a tractable ratio of $\frac{b}{a}$ equal to unity, the amount of calculation involved in the solution offered by the author is very great; and it is probably for this reason that Professor Young resorted to the "roughing in" of the curves denoted by 5(*a*) in Figs. 6 and 7. For determining the character of these curves, a single control point and two limiting curves were available.

Because of the amount of computation involved, any approximate solution that will give sufficiently accurate values with less computation is to be welcomed. Such an approximate solution is available[14] and the relative accuracy of the two can be compared. Unfortunately the Marcus approximate method was applied to the ratio $\frac{b}{a} = 0.5$ for case (*a*), Fig. 5, and the results for this case must be compared with values from Curves 5(*a*) of Figs. 6 and 7 which are approximate. Moreover, the Marcus method was applied to case (*b*), Fig. 5, and Table 2 shows the values obtained by Marcus for cases (*a*) and (*b*) compared with those taken from the curves of Figs. 6 and 7.

TABLE 2.—Comparison of C for $b/a = 0.5$

Method	C_1		C_2	
	Fig. 5(*a*)	Fig. 5(*b*)	Fig. 5(*a*)	Fig. 5(*b*)
Young....	0.102	0.064	0.049	0.036
Marcus...	0.082	0.063	0.042	0.039

It is seen that the results of the author's method and the Marcus approximate solution agree fairly well for case (*b*), but there is quite a discrepancy in the values given for case (*a*), Fig. 5. Since the Young values are taken from a curve that is "roughed in," no definite statement can be made concerning the accuracy of the Marcus method until a mathematically exact solution is made of curves 5(*a*), Figs. 6 and 7, using the Young method. However, the comparison of the values for case (*b*) would seem to indicate that the Marcus method can be relied upon. Another distinguishing feature is that the Marcus solution for $b/a = 0.5$ shows that the maximum value of M_x occurs at $x \doteq a/2, y = b/4$, and its value is $0.050\,\gamma\, b^3$

As the author states, the solution given in the paper can be applied to counterforted walls subjected to hydrostatic pressure by assuming constant thickness and fixity at the base and counterfort. An interesting problem is the analysis of the part of the counterforted wall, ABCD (Fig. 8(*a*)). Not only are the questions of moments and shears of interest, but the following question may be posed: What must be the ratio of b/a so that the deflection of line AD shall be sensibly the same as that of a cantilever of the same height?

The writer has applied the Marcus method to such a plate ABCD of Fig. 8(*a*) with b/a = unity and obtained results as shown in Fig. 8(*b*). For ratios $b/a < 1$ the Marcus method is not satisfactory when applied to plates ABCD of Fig. 8(*a*), and Marcus states that the computations become tedious for $b/a < 0.5$ when applied to walls of cases (*a*) and (*b*), Fig. 5.

FIG. 8

DANA YOUNG,[15] M. AM. SOC. C. E.—The comparative data presented by Mr. Silverman in Table 2 are very interesting, and it is satisfying to see that the results are in reasonably close agreement. In drawing the curves 5(*a*) of Figs. 6 and 7, an attempt was made to provide design data that would be on the safe side. The significant fact is that the actual moments are considerably less than for a vertical or horizontal beam strip.

The calculation of plates under any except the simpler boundary conditions is at best a tedious task, and it is not expected that the detailed calculations should be made by every designer. Fortunately, it is not necessary to do so, any more than it is necessary for a designer to integrate the equation of the elastic curve every time he wishes to know the moments in a clamped beam. A table of moments for all useful cases is what is needed; the results given represent a start in this direction.

DESIGN OF SIGN LETTER SIZES

BY ADOLPHUS MITCHELL,[1] ASSOC. M. AM. SOC. C. E., AND
T. W. FORBES,[2] ESQ.

WITH DISCUSSION BY MESSRS. GUY KELCEY, CHARLES M. NOBLE, AND
ADOLPHUS MITCHELL AND T. W. FORBES.

SYNOPSIS

There has been a growing interest and attention among traffic engineers, and others, in improving the design of highway warning and destination signs. The effectiveness and usefulness of the highway are increased by proper signs just as the proper use of a mechanical article of merchandise is insured by clear and adequate instructions on the box.

There are two characteristics of properly designed highway signs: (1) They must be readable and they must give the motorist sufficient warning to permit making the maneuver comfortably; and (2) they must be designed so as to gain the motorist's attention. To gain attention (characteristic (2)) is a complex problem which deserves separate treatment and is beyond the scope of this paper. Since certain standard color combinations are now agreed upon by state and national highway agencies, these standard color combinations will be assumed in the paper.

FUNDAMENTAL FACTORS IN LETTER SIZE

On the basis of measurements that have been made of the various factors resulting in the readability, or legibility, of a sign, it is possible to derive methods and formulas for practical determination of the minimum letter size necessary to make them effective under given traffic conditions on the highway.

It is obvious that the size of the letters must depend not only on traffic characteristics (since drivers need more warning at high speeds), but also upon vision because the effectiveness of sign copy depends upon what the driver can see. Knowledge is now available from studies of these various factors to set up a method of the size of letters on highway signs. To compute the size of a letter for a highway sign it is necessary to consider design speed, the location of the

---

NOTE.—Published in January, 1942, *Proceedings*.

[1] Senior Traffic Engr., State Highway and Public Works Comm., Raleigh, N. C.

[2] Bureau for Street Traffic Research, Yale Univ., New Haven, Conn.

sign, warning time, type of letter (letter proportion), and legibility distance. The following sub-factors influence the determination of warning time: Time for the minimum glance, safety factor in case the sign is not seen at the first possible moment, perception-reaction time, and stopping or deceleration time as necessitated by circumstances.

Design Speed.—Design speed may be defined as that speed at, or below which, a certain proportion of the vehicles operate at the location in question. The proportion (or percentile speed) used by different engineers has ranged from 80% to 90%,[3] and D. W. Loutzenheiser, Jun. Am. Soc. C. E., in 1940, reported[4] an analysis of speed data in an attempt to derive a similar definition for the design application. This report indicates that at least a 90 percentile speed is desirable. Since the higher percentile value results in a higher speed and a longer warning distance, it represents the conservative choice; and the 90 percentile speed of vehicles operating on the highway at the point to be signed is to be recommended for the design of sign-letter size.

Obviously, it is not practicable to make a "spot speed study" at all points along the highway, and since most highways in open country show similar speed characteristics throughout certain sections, it is sufficient to use one speed determination for such sections and another for special conditions, such as suburban and congested urban conditions. At special locations, such as curves, the techniques now in use for speed zoning would be continued. Thus the spot speed check might be replaced by the use of a speed determination from the ball bank indicator, calibrated for such special application.

Sign Location.—The position of the sign on the highway will influence the necessary letter size longitudinally and laterally. In the first place, the sign placed ahead of the hazard will allow the use of a smaller letter size, whereas one at or behind the hazard will require a larger letter size if the driver is to see it at a given distance or warning time away. In the second place, the lateral placement of the sign will influence the point at which the driver's gaze must leave the sign and return to the road. Longitudinal placement is illustrated diagrammatically in Fig. 1. If the driver of vehicle 1 is to read the sign at the position indicated, and if *O* represents the point of hazard or the point at which the maneuver must begin, a sign placed at a distance *A* ahead of this point will require a smaller letter size than a sign placed at a position *A′* behind this point.

Therefore the distance A may be subtracted or the distance A' added to the necessary warning distance in deriving the necessary legibility distance.

Whether the signs should be placed at position A' or at position A involves the question of attention values, which is beyond the scope of this paper. The lateral position of the sign affects the "cutoff" point of the driver's vision as illustrated in Fig. 1 by the position of vehicle 2. At this point, the line of sight, as the driver is looking at the sign, will form angle α with the center line of the lane of travel as shown. If the maximum allowable angle α is known, the position of vehicle 2 beyond which the driver's line of sight must leave the sign and return to the road can be determined; thus:

$$C = B \cot \alpha \quad \text{.........................(1)}$$

in which B is the distance in feet from the sign to the center line of the traveled lane. The clearest seeing occurs[5] in a small zone in the center of the visual field which is delimited by an optical angle of about 5°. In the area just outside of this 5°, the degree of clear vision reduces rapidly until at about 10° (5° to either side of the line of sight) there is a sharp break in the acuity curve indicating that in a position more lateral than this, the vision experienced in the periphery of the eye is of the fuzzier type. The driver ordinarily glances about the landscape with short quick eye movements, resembling flashes of a highly focused spot light or search light.[6] A practical value for the angle α may be obtained on the basis of allowing two minimum 5° eye movements to the side of the center line of the traveled lane. This will allow some part of the traveled lane to remain in the 10° cone of fairly clear vision up to about 50 ft ahead of the car.

Then, assuming $\alpha = 10°$, Eq. 1 becomes

$$C = B \cot 10° = 5.7\,B \quad \text{....................(2)}$$

From this relationship, if B is 17.5 ft (one half of the 10-ft lane plus a 10-ft shoulder, plus 2.5 ft from the shoulder to the center of the sign) the distance C will be approximately 100 ft. This gives a rule-of-thumb idea of the magnitudes involved. The hypothetical position of vehicle 2 should be in the lane most unfavorable for vision of the sign in the location in question.

Warning Time.—The importance of thinking in terms of time in order to allow the driver sufficient warning has already been mentioned. Since the process of reading, as well as the perception and reaction of the driver, may be assigned fairly definite time values, and since the use of time values automatically corrects for the greater distance at higher speeds, they are fundamental. If sufficient warning time is given the driver and if he is duly impressed with the nature of the hazard to which he is coming, he will be able to operate comfortably and without any surprise element. To be adequate, warning time must allow for: (1) Minimum time for reading, (2) a safety factor in case the sign is not seen at the first possible instant, (3) perception-reaction time, and (4) stopping or deceleration time necessary for the maneuver involved. Ordinarily, the first three of these time values (those in connection with reading and perception reaction) will pass before any slowing occurs. Therefore, they may be treated as pure time values and converted into distance values by multiplying by the design speed.

[5] "Textbook of Physiology," by W. H. Howell, W. B. Saunders Co., Philadelphia, Pa., 1940.

[6] *Transactions*, Am. Soc. C. E., Vol. 106 (1940), p. 456.

Minimum Reading Time and Safety Factor.—The shortest possible glance from the road to read the sign and back to the road consumes from 0.6 to 1.0 sec. During this glance the maximum amount of copy which can be read by the ordinary person is from three to four familiar words.[7] This time value results from the fact that it takes approximately 0.2 sec for the eye to stop, focus and read, and another 0.2 sec for the eye to start and move through one of the 5° or 10° jumps. To be conservative, therefore, 1.0 sec is adopted as the time necessary for a single minimum glance from road to sign and back to the road, allowing the shortest possible glance at both the road and the sign.

If more than three familiar words are included in the copy, it has been shown that the time for reading the sign may be increased to as much as from 3 to 11 sec,[8] and such signs, therefore, are impracticable on high-speed highways. Where they are unavoidable the reading time should be increased by one second for each additional three or four familiar words, thus making allowance for the driver to glance back to the road between glances at the sign.

It is still necessary to add a time interval as a safety factor in case the sign is not seen at once. The smallest possible safety factor is one 1-sec glance; that is, the minimum reading time is 2 t_g, in which t_g is the time required for a single glance or 1.0 sec and when signs contain the minimum number of words. When the sign contains more than three words:

$$t_g = \frac{N}{3} + 1.0 \qquad (3)$$

in which N equals the number of familiar words on the sign. If the attention or target value has been properly designed into the sign, the motorist will have seen it before he is able to read it, and Eq. 3, with 2 sec as an absolute minimum, will guarantee him time to read the sign twice unless something distracts him or obstructs his vision.

Perception-Reaction Time.—It takes time for the human nervous and muscular system to react, just as it takes time to complete a call through the telephone exchange. This time value increases as the complexity of the process increases, so that there is a range of time values that may be classified under three headings in order of magnitude—that is, simple brake-reaction time such as that in an emergency situation (from 0.5 to 0.7 sec),[9] perception-reaction time in ordinary traffic situations of medium complexity, and finally, judgment perception-reaction time (2.8 to 3.5 sec).[10]

The perception-reaction time needed to observe signs is intermediate between the simple reaction time and the complex skilled judgment that involves the longest time interval. Interpolated between the values of these two, it will not be far in error to assume a perception-reaction time of 1.5 sec for sign design.

Deceleration Time.—Consider a point at which some vehicles are decelerating (case 1) while others are continuing with practically no change of speed. This case is best illustrated at grade-separated intersections where some drivers are decelerating and turning off while others are going on through the intersection. Obviously, those drivers who wish to turn off must have the time and distance to decelerate comfortably; and at the same time those who proceed at initial velocity must have sufficient warning to choose the correct lane and to avoid incoming and outgoing vehicles. Somewhat similar conditions hold for intersections at grade on low-volume high-speed highways.

A report by John Beakey,[11] in which the speed checks were made on vehicles approaching a stop sign at a rural intersection, indicates that the general driving public utilized approximately 10 sec on the average for decelerating from 55 miles to 20 miles per hr. If the deceleration times for lower initial speeds as reported in this study are examined, it will be found that deceleration to 20 miles per hr in each case approximated 8 sec. These measurements would seem to justify the use of a value of 8 to 10 sec for comfortable deceleration time on most highways. Since this paper is dealing with the minimum values for necessary warnings, the lower value of 8 sec will be adopted. Deceleration to 20 miles per hr was chosen as being applicable in the majority of highway intersection applications. Time values for higher final speeds are given elsewhere.[11]

Regardless of the speed at which they are operating or the point at which they begin their deceleration, various motorists whose vehicles were checked give themselves about the same time to decelerate. The motorists traveling at 30 miles per hr or less could have decelerated in a shorter time if they had desired. It may be assumed, therefore, that 8 sec represents a comfortable time to the motorist and that where a vehicle is proceeding straight through at ordinary speed, a similar time interval should be allowed for weaving and dodging incoming or outgoing cars. Since the through speed will be V_i (which is assumed as 55 miles per hr), it will always be a higher velocity than the average velocity $\frac{V_i + V_f}{2}$. Therefore, $t = 8$ sec and V_i for determining warning distances will allow sufficient time and distance for both the high speed and the decelerating vehicles.

When all cars must come to a stop (case 2), the stopping distance is the controlling factor, but it must be borne in mind that the value of deceleration used must be such as to allow the motorist 8 sec or more in order to satisfy the time requirement for comfortable operation as derived for the case of simple deceleration without stopping. Transforming Eq. 3,

$$t = \frac{1.47\,(V_i - V_f)}{a} = 8 \text{ sec} \ldots\ldots\ldots\ldots\ldots\ldots \quad (4)$$

in which V_i is in miles per hour, V_f equals zero, and a is deceleration in feet per second per second.

---

[11] "Acceleration and Deceleration Characteristics of Private Passenger Vehicles," by John Beakey, *Proceedings*, Highway Research Bd., Vol. 18, 1938, Fig. 9, p. 81.

MANEUVERING OR DECELERATION DISTANCE

Case 1.—For this case, utilizing the foregoing values for simple deceleration time, the maneuvering distance D is as follows:

$$D = 1.47\ V_i t = 8 \times 1.47\ V_i \qquad (5)$$

in which V_i is the design speed (90 percentile speed of approach and of through vehicles) in miles per hour.

Case 2.—If the distance necessary to stop comfortably results in a corresponding stopping time greater than that shown (case 2), the stopping distance may be used for computing the total warning distance. Deceleration and stopping distance is given by the following familiar formula:[12]

$$s = \frac{(1.47)^2\,(V^2_i - V^2_f)}{2\,a} \qquad (6)$$

in which V_i is initial velocity in miles per hour, V_f is the final velocity at deceleration (which becomes zero for a stopping distance), and a is the deceleration in feet per second per second. The stopping distance thus becomes:

$$s = \frac{1.08\ V^2_i}{a} \qquad (7)$$

To determine comfortable stopping distances for sign-design purposes, it is necessary to choose a value of deceleration a that will fulfil several conditions. It must result in comfortable stopping, must allow the motorist sufficient warning time, and must fulfil the requirements of safe stopping under adverse surface conditions, such as ice, snow, and wet pavements. In other words, the distance allowed the motorist should be adequate under all conditions. Mr. Beakey's study shows a time of 12 sec for a stop from 55 miles per hr, which corresponds to an average deceleration value a of 6.8 ft per sec². However, the actual instantaneous deceleration from which this average value was computed ran as high as approximately 12 ft per sec² as the vehicle approached the actual stopping point. A report by E. E. Wilson[13] in 1940 indicates 8.6 ft per sec² to represent a comfortable (average) deceleration as reported by drivers and passengers in stops from 50, 60, and 70 miles per hr. Thus, from 6 to 8 ft per sec² as an average deceleration apparently represents the comfortable deceleration range chosen by motorists. Maximum instantaneous values will be much higher, of course, but this does not concern the present application.

It is recommended that an average deceleration value of 4 ft per sec² be used for designing sign letters. This will maintain the maneuvering time in the 8-sec range indicated by Mr. Beakey's study for the lower speeds. For instance, in computing stopping distance from 30 miles per hr, 8 ft per sec² gives $t = \frac{1.47 \times 30}{8} = 5.5$ sec, which is an inadequate time value. The deceleration of 4 ft per sec² raises this value to 11 sec, which is adequate. Furthermore, since this value corresponds to a coefficient of friction of about $f = 0.12$, it should be adequate for icy conditions.[13] Therefore, the sign design value recommended is $a = 4$ ft per sec^2.

WARNING DISTANCE

Having now determined all the components of warning time and warning distance and explained the basis upon which they have been derived, it is possible to assemble the factors to yield the total warning time and warning distance, in Figs. 1 and 2.

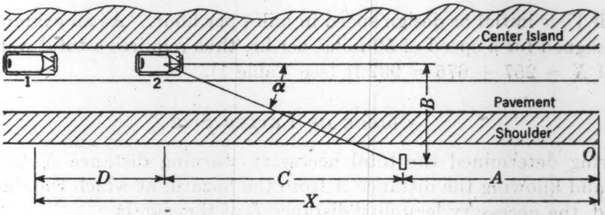

FIG. 2

Case 1.—For case 1 the total warning time T is given by

$$T = 2\,t_g + t_p + t_d \qquad (8)$$

in which t_g is the time for a single glance at a sign, t_p is perception-reaction time, and t_d is deceleration time. Assuming phrases of not more than three familiar words and substituting the value derived previously, this becomes $T = 2.0 + 1.5 + 8.0 = 11.5$ sec. When the sign contains a greater number of words, the first term must be increased accordingly.

The total warning distance then becomes

$$X = 1.47\,V_i\,T = 1.47 \times 11.5\,V_i \qquad (9)$$

in which V_i is the sign-design speed of the highway, and T is the total warning time. For convenience, it is suggested that the time value be rounded off to 11 sec, giving $X = 16.2 \times V_i$ in miles per hr, or $X = 11 \times V_i$ in ft per sec. This will yield a warning distance in which the sign placement and design should allow the sign to be read at 810 ft for a design speed of 50 miles per hr. Other values are given in Table 1.

TABLE 1.—TYPICAL WARNING DISTANCES, X, IN FEET[a]

Deceleration distances required to:	VELOCITY, V_i, IN MILES PER HOUR			
	30	40	50	60
Enter an intersection at 20 miles per hr	486	648	810	972
Stop at an intersection	393	638	932	1,281

[a] Level grades have been assumed throughout.

Case 2.—When all cars must stop at or before the hazard, the total warning distance may be computed as follows:

$$D = 1.47\, V_i\, (2\, t_g + t_p) + s \quad \ldots\ldots (10)$$

in which s is the stopping distance defined by Eq. 7. Substituting the values derived in the foregoing sections:

$$X = 1.47\, V_i \times (2.0 + 1.5) + \frac{1.08\, V^2_i}{a} = 1.47\, V_i \times 3.5 + \frac{1.08\, V^2_i}{4} \ldots (11)$$

in which V_i is initial or design speed in miles per hour. As an example, a stop sign, designed for a speed of 50 miles per hr, thus requires a total warning distance of $X = 257 + 675 = 932$ ft (see Table 1).

CHOICE OF LETTER SIZE

Having determined the total necessary warning distance X (see Figs. 1 and 2) and knowing the distance A from the hazard, at which the sign is to be installed, the necessary legibility distance L of the sign is

$$L = X - A = C + D \quad \ldots\ldots (12)$$

Legibility distances for letters of different widths[14] have been determined in an extended series of tests using from 100 to 250 different people as observers.[15] The findings for daylight conditions may be briefly summarized as follows:

U. S. standard series	Width	Letter legibility, l, in feet per inch of letter height
B	Narrow	33
C	Medium	42.5
D	Wide	50

Dividing the necessary legibility distance (L) by the appropriate letter legibility (l) gives the letter size indicated; thus:

$$\frac{L}{l} = H \quad \ldots\ldots (13)$$

in which H is the letter height of that particular design letter needed.

Again illustrating, if $X = 932$ ft, $A = 400$ ft, and a wide letter is to be used: $H = \frac{932 - 400}{50} = \frac{532}{50} = 10.6$ in., and a 12-in. letter is indicated. Since it is quite possible to locate a sign so far in advance of the hazard that this computation would call for an absurdly small letter height, the position chosen for locating the sign must be checked. The distance D must be great enough to allow at least minimum reading time (see Eq. 3). Therefore, from Fig. 2,

---

[14] "Manual on Uniform Traffic Control Devices for Streets and Highways," A.A.S.H.O. and National Conference on Street and Highway Safety, Washington, D. C., 1937.

[15] "Legibility Distances of Highway Destination Signs in Relation to Letter Height, Letter Width, and Reflectorization," by T. W. Forbes and R. S. Holmes, *Proceedings*, Highway Research Bd., 1939, Vol. 19, p. 321.

$$D = X - A - C = X - A - \text{cotan } 10° \ldots\ldots\ldots\ldots (14)$$

For a sign with three words or less, $D \overset{=}{>} 1.47\ V_i \times 2\ t_g$.

Case 1.—When some cars proceed, some decelerate, but none must stop, the design speed is determined first by computing X from Eq. 9, or reading it from Table 1. If the sign is to be 400 ft ahead of the hazard ($A = 400$) the necessary legibility distance $L = X - 400$ ft. Next obtain the legibility per inch of letter height (l) from the text (see heading "Choice of Letter Size").[15] The letter height $H = \frac{L}{l} = \frac{X - 400}{l}$. To check for sufficient reading time, obtain C by Eq. 2. Then the following condition must hold (see Eq. 13): $D = L - C \overset{=}{>} 1.47\ V_i \times 2\ t_g$.

For 3-word or 4-word signs, this becomes $1.47\ V_i \times 2$. For more words, t_g should be increased as shown in Eq. 3.

Case 2.—Where all vehicles must stop, the design speed is determined as before; the total warning distance X is computed from Eq. 11 or Table 1; and A or A' is subtracted or added, respectively. Again suppose it is desired to place the sign 400 ft ahead of the hazard; then $L = X - 400$ and the letter height $H = \frac{X - 400}{l}$, in which l is legibility distance of the letters to be used.[15] Finally, the designer should check for sufficient reading time as in case 1. In both cases, if the reading time is too short, determine A, or the sign location, by reversing the last few steps. Obtain D from Eq. 14, C from Eq. 2, and $A = X - (C + D)$. The sign must be mounted at the position indicated. Finally, compute L and H for the new sign position by the appropriate method for either case 1 or case 2.

Practical Considerations

Obviously certain practical decisions as to where the sign is to be placed, whether both pre-warning and a sign at the hazard or intersection are necessary, and similar questions must be answered before the necessary letter height can be determined. Furthermore, in choosing which of the standard alphabet series to use for the sign copy the designer must take into consideration such factors as the length of place names involved and the general shape and limiting dimensions allowable for his sign. In certain cases where practical requirements make it necessary to include more than three words in a given sign, it has been found desirable to use two different letter sizes in the copy. A larger size has been used for certain important words intended to be read at the greatest distance and a smaller size for the less important legend intended to be read at a closer position and with a second glance of the driver's eye.[16]

Summary

A method has been described for determining the necessary letter size for effective highway sign design in terms of warning time, warning distance, and a

---

[16] Sign Specifications of the Pennsylvania Turnpike Commission, Missouri State Highway Dept., and others.

90 percentile design speed. The increased warning distance necessary at higher speeds has been provided through the use of driver warning time as the basic consideration. Appropriate braking distances have been introduced where necessary.

Table 1 (or Eqs. 9 and 11) furnishes values for convenient computation of the letter height needed, and a simplified outline of procedure is given in the paper.

By use of such a method, it is possible to fit the sign to the highway and the driver and to obtain consistently effective signs for widely varying conditions of velocity and sign location with respect to the hazard or the maneuver point.

DISCUSSION

Guy Kelcey,[17] **M. Am. Soc. C. E.**—In their presentation of this too little explored subject, Messrs. Mitchell and Forbes have made a definite contribution in the direction of more efficient and, therefore, of safer roadway usage. Although the subject presented may be of quite limited interest to many engineers, it is of great importance to those who are responsible for best use of roadways for purposes of transportation.

A traffic sign has two values. A driver's attention is attracted to a sign, before he is within its legibility range, by its target value. At closer approach he is able to read its message or to perceive its symbol. If sign copy is too small to be useful to high-speed traffic, except at very close range, special attention must be given to the target value of such signs by the use of conspicuous background colors and shapes, such as octagon, round, square, or diamond, so that the target characteristic of the sign will tell drivers from a distance what general type of road condition is ahead. When, as Messrs. Mitchell and Forbes suggest, sign copy is enlarged so that its legibility has adequate distance value, in terms of the present-day speed characteristics of the location, target value, beyond that provided by the copy or symbol, becomes of lesser or of no importance.

This leads to an interesting conclusion. In the past, traffic sign design has tended to ignore legibility value and copy was condensed into standard sized target space. Pursuit of the principles presented by Messrs. Mitchell and Forbes would reverse this procedure. It would result in designing to legibility value and then adapting the size and shape of the sign background to the resulting copy dimensions. Since the copy or symbol would be large enough to provide any target value needed, no great attention need be paid to providing target value in the sign background. If so, the most conspicuous colors could be used in the copy or symbol and even greater legibility values achieved.

The practice of placing traffic signs in advance of the point to which their message applies is regarded by some as a needless carry-over from conditions of many years ago. Painted signs were originally placed in advance of hazards largely because they could not be read at night until a driver was close; he then needed some distance—generally 300 ft—in which to act. This practice of advance location of traffic signs lost its major purpose with the introduction of reflectors and other means to illuminate copy for legibility from a distance after dark.

Just as a lantern is best placed directly on a pile of brick in a street and not 300 ft in advance, there is much to be said in favor of placing a luminous or illuminated warning or information sign at, or close to, the point to which its message applies. Thus, the message is not only projected to drivers at a distance, but the drivers are brought all the way up to the point to which the message applies.

---

[17] Atlanta, Ga.

It is generally overlooked, too, that the location of signs well in advance of a hazard often introduces a danger. Like a structural worker walking high steel, a good driver looks up and not down. His gaze is normally focused several hundred feet or more ahead. When a traffic sign, with copy legibility of from 200 to 300 ft, comes into view, a driver reads its message from or near that distance and the focus of his attention sweeps on. If this distance is added to the 300 ft that the sign is placed in advance of the danger, it will be noted that it is possible for a driver, whose attention is focused on the road in front, to travel the last 500 ft or more with no further reminders of the condition ahead unless the danger itself is conspicuous. At night a driver can and often does forget the message on signs placed in advance of danger points, and being unable to see the hazard ahead, is taken by surprise.

Messrs. Mitchell and Forbes present a method by which sign copy size requirements may be determined accurately for each sign location, thus to provide adequate legibility values to satisfy determined conditions. In practice it should be possible to establish a series of copy sizes in 3-in. or in 6-in. steps and to use the nearest suitable size. Tailor-made traffic signs, with copy exactly proportioned to variable legibility distance needs, could result in a multiplicity of copy dimensions that would increase the cost of manufacture and of inventory and complicate installation and maintenance.

Free space available adjacent to the traveled part of roadways and streets is often so limited that signs, larger than those now used, could not always be accommodated if installed in accordance with present standards. If legibility values greater than those provided by currently standard sign copy are to be employed, it will be recognized that much larger traffic signs would be used. If so, in many cases, they must either be suspended over the roadway or bracketed over the shoulder or the sidewalk. Indeed this has already been done at scattered locations in some jurisdictions and results are reported to be excellent.

Charles M. Noble,[18] M. Am. Soc. C. E.—Marking the second step in the development of highway sign technique, it is hoped that this paper will stimulate interest in continuing the advance in research in order that complete practical scientific data will be available to the highway and traffic engineer.

The use of adequate signs is becoming increasingly important due to the advancing development of modern highway design that utilizes the principle of free flowing traffic. This principle, involving as it does the elimination of cross traffic and left turns by the use of grade separations with right turns only, results in a type of highway facility that is confusing to the uninitiated motorist in that he is required to turn right when he wishes to go left. Turning right in order to "go left" is contrary to the instincts of the average motorist. Consequently, it is of the utmost importance that directions (the sign) be of such design, size, and clarity that the driver will have ample time to observe, read, react, and maneuver properly. The modern "cloverleaf" is designed on the assumption that the motorist will make the proper turns, and he must do so if he is to avoid losing valuable time and "getting lost." Adequate signing is fundamental, therefore, if the economic value of the expensive grade-separated type of highway is to be fully realized; and the utmost care and thought should be given to the design and placement of highway direction signs.

---

[18] Arlington, Va.

The authors have presented, step by step, a logical reasoning in an analysis for determinating the correct letter sizes to be used in designing a sign for particular conditions of design speed and site location. The principle of breaking the elements of reading, perception, and reaction into units of time which in turn can be converted into distance and then related to the distance at which various sized letters can be read by the motorist, is fundamentally sound. (Incidentally the table in the paper which presents the visibility distances of letters is based on the eighty percentile group of motorists.)

A study of the material presented reveals that letters of a much larger size than customarily utilized should be used if the highway sign is to be fully effective. These large letters when assembled together into a sign message will result in a sign panel of such dimensions that it will stagger the designer when compared with ordinary standards. In this connection it is interesting to note that some of the direction signs on the Pennsylvania Turnpike are 14 ft wide by 9 ft high and these signs do not give the impression of being oversize for the conditions. The practice of utilizing letters of different size on the same sign, as outlined by the authors, was adopted successfully on the Turnpike, and it is believed that this is a practical method of keeping the size of the sign panel within reasonable bounds.

The analysis by the authors indicates that a smaller size of direction sign may be utilized if the sign is placed in advance of the turnout rather than at the point of turnout. For example, at a speed of 50 miles per hr an advance sign must be seen for a distance of 530 ft (six-lane highway width) requiring 12-in. series D letters, whereas a sign placed at the point of turnout should be seen a distance of 870 ft requiring 18-in. series D letters.

These required distances lead to a complication when signing urban highways in congested metropolitan areas where turnouts are frequent and often very close together with insufficient distance available to satisfy the requirements of speed and vision. Such conditions will tax the ingenuity of the sign designer.

The authors have covered the subject admirably, having placed a new tool in the hands of the engineer which will add to the effectiveness of the highway as well as to the safety and comfort of the traveling public, and have therefore performed a valuable service.

ADOLPHUS MITCHELL,[19] ASSOC. M. AM. SOC. C. E., AND T. W. FORBES,[20] ESQ.—It was hoped that more discussions would be written; but, since the two published were by men who are leaders in this field, it may be said that the lack of quantity was made up for by the quality.

[20] Stevens Inst. of Technology, Hoboken, N. J.; formerly Bureau for Street Traffic Research, Yale Univ., New Haven, Conn.

In closing, it appears to be in order to restate that it was not intended, in the paper, to discuss the attention-getting properties of signs. This element in sign work usually will determine the location of the signs. After the position of each sign has been determined, the sign letter sizes can be designed in accordance with the principles stated in the paper.

The writers wish to thank Messrs. Kelcey and Noble for their fine discussions.

Paper No. 2178

LATERAL STABILITY OF UNSYMMETRICAL I-BEAMS AND TRUSSES IN BENDING

BY GEORGE WINTER,[1] ESQ.

WITH DISCUSSION BY MESSRS. ROBERT K. SCHRADER, H. N. HILL, AND GEORGE WINTER.

SYNOPSIS

An analysis is given herein of the lateral stability of unsymmetrical I-beams, both free and horizontally restrained along the bottom edge, and of beams of rectangular cross section horizontally restrained along the bottom edge. The cases of horizontally restrained beams apply to sheet stiffeners in bending. It is explained that the torsional rigidity of trusses and of thin-wall I-beams is smaller than would be expected from the use of the usual formulas for torsional stiffness. This is due to the fact that horizontal bending of such elements is accompanied by distortion of the cross section. For this reason, it is suggested that satisfactory, although slightly conservative, estimates of the critical loads of such beams may be obtained by neglecting the torsional rigidity entirely.

THE PROBLEM

The solutions of the problem of lateral instability of beams known in the literature do not cover the entire range of cases arising in practice. A few of these are:

(1) The general case of an I-beam non-symmetrical about its horizontal axis;

(2) The case of beams of various cross sections horizontally restrained along the tension edge (this situation is realized for sheets stiffened by projecting ribs and subject to bending in such a way that the sheet is in tension); and

(3) The lateral stability of trusses and of I-beams made of thin sheet metal.

These problems are analyzed herein for the case of pure bending and for the case of a simple beam with a concentrated load at the center of the span, applied at any arbitrary level.

NOTE.—Published in December, 1941, *Proceedings*.

Notation.—The letter symbols in this paper are defined where they first appear, and are assembled for reference in Appendix I.

METHOD

The work-energy method is used throughout this investigation. The horizontal displacement of the beam due to lateral instability is resolved into two components (Fig. 1): A horizontal bending displacement y of the flexural center, and a rotation ϕ about a horizontal axis through the flexural center.

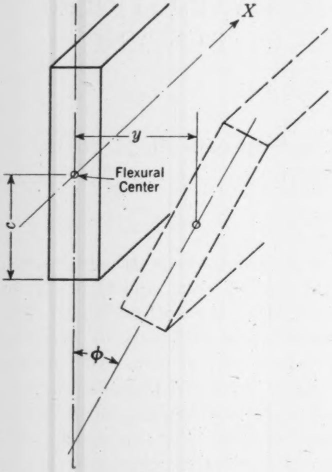

FIG. 1

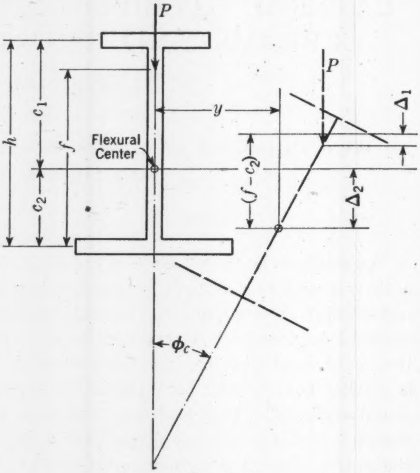

FIG. 2

The angle ϕ is an unknown function of the longitudinal ordinate x (origin at one of the supports). The beam is assumed to be supported in such a way that rotation of the end sections about the longitudinal axis of the beam is prevented. Consequently, the condition that must be satisfied by ϕ at the ends is: $\phi = 0$ at $x = 0$ and $x = L$.

Empirically it is known that, after loss of stability, the horizontal deformation of the beam has the form of a single half wave. This general character is represented and the boundary conditions are satisfied by taking

$$\phi = a \sin \frac{\pi x}{L} \qquad \text{(1)}$$

in which a = a coefficient modifying the total angular deformation ϕ (see Eq. 1); and L = span length.

The assumption of this approximate form of $\phi(x)$ involves a certain error, the magnitude of which could be estimated by expanding $\phi(x)$ in a Fourier series with unknown coefficients instead of taking only the first term of such a series. Without making use of this elaborate procedure it will be shown by comparison that the error involved is negligible for all practical purposes.

VALUES OF INTEGRALS FREQUENTLY ARISING IN THE ANALYSIS

To simplify the mathematical presentation, the solutions of definite integrals which will frequently appear in the following pages are given as follows:

$$\left.\begin{aligned} \int_0^L \phi^2\,dx &= \frac{a^2\,L}{2} \\ \int_0^L \left(\frac{d\phi}{dx}\right)^2 dx &= a^2\,\frac{\pi^2}{2\,L} \\ \int_0^L \left(\frac{d^2\phi}{dx^2}\right)^2 dx &= a^2\,\frac{\pi^4}{2\,L^3} \\ \int_0^{L/2} \phi\,\frac{d^2\phi}{dx^2}\,x\,dx &= -\frac{a^2}{4}\left(1+\frac{\pi^2}{4}\right) \\ \int_0^{L/2} \phi^2\,x^2\,dx &= \frac{a^2\,L^3}{8\,\pi^2}\left(1+\frac{\pi^2}{6}\right) \end{aligned}\right\} \ldots\ldots\ldots\ldots\ldots (2)$$

I-BEAMS ASYMMETRICAL ABOUT THE HORIZONTAL AXIS

(*a*) *Pure Bending.*—For such beams the location of the flexural center is given by:[2]

$$c_1 = h\,\frac{I_2}{I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3a)$$

and

$$c_2 = h\,\frac{I_1}{I} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (3b)$$

in which (see Fig. 2) c_1 and c_2 are the distances to the flexural center from the centers of the compression and tension flanges of the beam, respectively; $h = c_1 + c_2$ = the total effective depth; and I, I_1, and I_2, respectively, are the inertia moments of the total beam, the compression flange, and the tension flange with respect to the vertical axis of the web. In computing I the moment of the web about its vertical axis is neglected.

The strain energy of the beam due to lateral bending and rotation about its flexural center consists of three parts (Fig. 2): (*a*) The energy of bending of the compression flange corresponding to a horizontal deflection $y + c_1\,\phi$; (*b*) the energy of bending of the tension flange corresponding to a horizontal deflection $y - c_2\,\phi$; and (*c*) the torsional energy corresponding to a rotation of the entire beam through the angle ϕ. Consequently, the strain energy is

$$W_e = \tfrac{1}{2}\left\{E\,I_1 \int_0^L \left[\frac{d^2(y + c_1\,\phi)}{dx^2}\right]^2 dx \right.$$
$$\left. + E\,I_2 \int_0^L \left[\frac{d^2(y - c_2\,\phi)}{dx^2}\right]^2 dx + G\,K \int_0^L \left(\frac{d\phi}{dx}\right)^2 dx\right\} \ldots\ldots (4)$$

---

[2] "Formulas for Stress and Strain," by R. J. Roark, McGraw-Hill Book Co., Inc., New York, N. Y., 1938, p. 118.

or, by substitution of c_1 and c_2 from Eq. 3,

$$W_\epsilon = \frac{E}{2}\left[I \int_0^L \left(\frac{d^2y}{dx^2}\right)^2 dx + \frac{I_1 I_2}{I} h^2 \int_0^L \left(\frac{d^2\phi}{dx^2}\right)^2 dx + C \int_0^L \left(\frac{d\phi}{dx}\right)^2 dx \right] \quad (5)$$

In Eq. 4, K = the torsional constant for the given cross section, G = the shear modulus—

$$G = \frac{E}{2\,(1+\mu)} \quad (6)$$

and μ = Poisson's ratio. In Eq. 5, C, the reduced torsional constant, equals

$$C = \frac{K}{2\,(1+\mu)} \quad (7)$$

If M is the vertical bending moment, its horizontal component acting on the beam in the displaced position is $M_y = M\,\phi$ and

$$\frac{d^2y}{dx^2} = -\frac{M\,\phi}{E\,I} \quad (8)$$

Substituting this expression for $\frac{d^2y}{dx^2}$ and also the appropriate values for the integrals, one arrives at

$$W_\epsilon = E\,\frac{a^2}{2}\left(\frac{M^2}{E^2\,I}\,\frac{L}{2} + \frac{I_1 I_2}{I}\,h^2\,\frac{\pi^4}{2\,L^3} + C\,\frac{\pi^2}{2\,L}\right) \quad (9)$$

The only external forces acting on the beam are the moments M applied at the ends (Fig. 3). If β designates the vertical angle of rotation of each of the end sections due to the horizontal deformation of the beam, the work of the external forces is

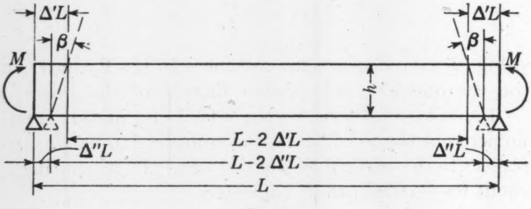

FIG. 3

$$W = 2\,\beta\,M \quad (10)$$

The magnitude of β is obtained by determining half of the difference in length of the chords of the horizontal curves formed by the axes of the top and bottom flanges in the laterally bent state ($\Delta'L - \Delta''L$ in Fig. 3). Thus,

$$\beta = \frac{1}{2\,h}\left\{ \int_0^{L/2} \left[\frac{d(y + c_1\,\phi)}{dx}\right]^2 dx - \int_0^{L/2} \left[\frac{d(y - c_2\,\phi)}{dx}\right]^2 dx \right\}; \text{ or}$$

$$\beta = \tfrac{1}{4}\left[2 \int_0^L \frac{dy}{dx}\,\frac{d\phi}{dx}\,dx + h\,\frac{I_2 - I_1}{I} \int_0^L \left(\frac{d\phi}{dx}\right)^2 dx \right\} \quad (11)$$

From Eqs. 1 and 8, however,

$$\frac{dy}{dx} = \frac{a\,M}{E\,I}\left(\frac{L}{\pi}\cos\frac{\pi\,x}{L}\right)\ldots\ldots\ldots\ldots\ldots\ldots(12)$$

Since $W = 2\,\beta\,M$ (Eq. 10) one obtains, by substitution of the appropriate values for the integrals,

$$W = a^2\frac{M}{2\,I}\left[h\,(I_2 - I_1)\,\frac{\pi^2}{2\,L} + \frac{M\,L}{E}\right]\ldots\ldots\ldots\ldots(13)$$

The critical moment is now determined from the work-energy condition, $W_\epsilon = W$, which results in

$$M_{cr} = E\,h\,\frac{\pi^2}{2\,L^2}\left[(I_1 - I_2) + \sqrt{I^2 + 4\,C\,I\,\frac{L^2}{\pi^2\,h^2}}\right]\ldots\ldots(14a)$$

For the case of a symmetrical I-beam with $I_1 = I_2 = I_0$, Eq. 14*a* reduces to

$$M_{cr} = E\,\frac{\pi^2}{L^2}\sqrt{I^2_0\,h^2 + 2\,C\,I_0\,\frac{L^2}{\pi^2}}\ldots\ldots\ldots\ldots\ldots(14b)$$

The exact solution for this latter special case has been developed by S. Timoshenko. If Professor Timoshenko's value of $\frac{a^2}{L^2}$ is substituted[3] in his comparable equation[4] for M_{cr}, the result is identical with Eq. 14*b*. In other words, for the case of pure bending, Eq. 1 happens to be the exact expression for $\phi(x)$.

(*b*) *Center Load.*—Eq. 5 for the strain energy remains the same as in the previous case. Between $x = 0$ and $x = \frac{L}{2}$,

$$\frac{d^2y}{dx^2} = -\,\frac{M\,\phi}{E\,I} = -\,\frac{P\,x\,\phi}{2\,E\,I}\ldots\ldots\ldots\ldots\ldots\ldots(15)$$

in which P = a vertical concentrated load applied at an arbitrary distance f from the bottom flange. Upon substitution of this expression the first integral in Eq. 5 becomes

$$\int_0^L\left(\frac{d^2y}{dx^2}\right)^2 dx = \frac{P^2}{2\,E^2\,I^2}\int_0^{L/2}\phi^2\,x^2\,dx\ldots\ldots\ldots\ldots(16)$$

If the corresponding values of the integrals are introduced, the strain energy in this case is

$$W_\epsilon = a^2\left[\frac{P^2}{E\,I}\,\frac{L^3}{32\,\pi^2}\left(1 + \frac{\pi^2}{6}\right) + h^2\,\frac{I_1\,I_2}{I}\,\frac{\pi^4}{4\,L^3}\,E + \frac{C\,E}{4}\,\frac{\pi^2}{L}\right]\ldots(17)$$

The vertical displacement of the force P, applied at an arbitrary distance f from the bottom flange, may be resolved into two components, Δ_1 and Δ_2.

---

[3] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., Eq. 157, p. 258.

[4] *Ibid.*, Eq. 159, p. 258.

The component Δ_1 (Fig. 2) represents the relative displacement of the point of load application with respect to the flexural center. It is easily seen geometrically that the amount of this displacement is

$$\Delta_1 = (f - c_2)(1 - \cos \phi_c) \ldots\ldots\ldots\ldots\ldots\ldots (18)$$

in which ϕ_c is the angle ϕ at the center of the span. Developing $\cos \phi$ in a power series in ϕ and, for a small value of ϕ, retaining only the first two terms:

$$\Delta_1 = a^2 \frac{f - c_2}{2} \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

The second component Δ_2 represents the relative displacement of the flexural center with respect to the supports caused by the horizontal curvature of the longitudinal axis of the beams through the flexural center. Thus

$$\Delta_2 = -\int_0^{L/2} \frac{d^2y}{dx^2}\, \phi\, x\, dx = \frac{P}{2\,E\,I} \int_0^{L/2} \phi^2 x^2\, dx \ldots\ldots\ldots (20)$$

Consequently, the work of the force P is $W = P(\Delta_1 + \Delta_2)$ or,

$$W = \left[\frac{P^2}{E\,I}\,\frac{L^3}{16\,\pi^2}\left(1 + \frac{\pi^2}{6}\right) + \frac{P}{2\,I}(f\,I - h\,I_1)\right] a^2 \ldots\ldots\ldots (21)$$

The critical load is again obtained by making $W_s = W$, which yields

$$P_{cr} = \frac{48\,\pi^2 E}{L^3(6 + \pi^2)}\left[(h\,I_1 - f\,I) + \right.$$

$$\left. + \sqrt{(h\,I_1 - f\,I)^2 + \frac{L^2(6 + \pi^2)}{48}\left(C\,I + \frac{h^2 I_1 I_2 \pi^2}{L^2}\right)}\,\right] \ldots\ldots (22a)$$

For the special case of the symmetrical **I**-beam ($I_1 = I_2 = I_0$) with P applied at the centroid $\left(f = \dfrac{h}{2}\right)$ this expression simplifies to

$$P_{cr} = \frac{12\,\pi^2}{L^2} E \sqrt{\frac{I_0}{3(6 + \pi^2)}\left(2\,C + \frac{h^2 \pi^2}{L^2} I_0\right)} \ldots\ldots\ldots (22b)$$

The exact solution for this special case in explicit form is not known to the writer. Using the energy method, Professor Timoshenko derived an integral equation[5] for this case. In solving it he uses only the first term of a Fourier expansion[6] which is identical with Eq. 1. It can be shown easily that, in this case, Professor Timoshenko's solution is identical with Eq. 22*b*. According to Professor Timoshenko, the error involved in taking this approximate expression for $\phi(x)$ amounts to only 0.5% in this special case. Without further detailed investigation it is reasonable to state that, in the general case of an unsymmetrical I-beam, loaded at any arbitrary level f, the error involved is of the same order of magnitude, and is therefore negligible for all practical purposes.

---

[5] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., Eq. e, p. 266.

[6] *Ibid.*, Eq. f, p. 266.

RECTANGULAR BEAMS HORIZONTALLY RESTRAINED ALONG THE TENSION EDGE

Imagine a simply supported rectangular beam restrained along its bottom (tension) edge in such a way that horizontal displacements are prevented, whereas vertical deflections remain entirely unaffected. This case is very nearly realized if, for some practical reason, horizontal bracing is applied only along the bottom edge. It is granted that such an arrangement in practice will be used only in exceptional cases. However, this problem is not only of general interest, but it leads to the analysis of the more important question of stability of sheet stiffeners of **I**-section and **T**-section, which will be treated subsequently.

(*a*) *Pure Bending.*—The horizontal displacement of the beam (Fig. 4) is again resolved into the horizontal deflection y of its flexural center and into a rotation about the same point. The general expression for the strain energy is then

$$W_\epsilon = \frac{E}{2}\left[I \int_0^L \left(\frac{d^2y}{dx^2}\right)^2 dx + C \int_0^L \left(\frac{d\phi}{dx}\right)^2 dx \right] \quad (23)$$

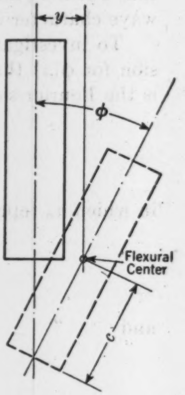

FIG. 4

As seen from Fig. 4 for small angles ϕ

$$y = c\,\phi \quad (24)$$

Substituting Eq. 24 in Eq. 23 yields

$$W_\epsilon = \frac{E}{2}\left[I\,c^2 \int_0^L \left(\frac{d^2\phi}{dx^2}\right)^2 dx + C \int_0^L \left(\frac{d\phi}{dx}\right)^2 dx \right] \quad (25)$$

On the basis of the same considerations as applied before to **I**-beams, the angle of rotation β of the end section is

$$\beta = \frac{1}{2\,c}\int_0^{L/2} \left(\frac{dy}{dx}\right)^2 dx = \frac{c}{2}\int_0^{L/2} \left(\frac{d\phi}{dx}\right)^2 dx \quad (26)$$

and the work of the external moments M becomes

$$W = 2\,\beta\,M = \frac{M\,c}{2}\int_0^L \left(\frac{d\phi}{dx}\right)^2 dx \quad (27)$$

It should be noted that in this case the moments M are not the only external forces acting on the beam. In fact, along the bottom edge horizontal forces are exerted by the restraint, which are of such magnitude that they prevent horizontal displacement of this edge. However, since the points of application of these forces are not subject to any displacement in the direction of the forces, they do no work. For this reason, Eq. 27 gives the total amount of work of the external forces.

It is well established, empirically and analytically, that laterally unrestrained beams buckle in a single half wave. For this reason it was legitimate to use Eq. 1 for an approximate representation of ϕ for free beams. However, in the case of beams restrained laterally along the bottom edge, it is possible that buckling may occur in more than one half wave. Buckling of such multiwave character is known to occur in thin plates, struts on elastic supports, etc.

To investigate this possibility, one must assume the most general expression for $\phi(x)$ that will satisfy the end conditions. Such a general expression is the Fourier series

$$\phi = \sum_{n=1,2,\cdots}^{\infty} a_n \sin \frac{n\,\pi\,x}{L} \tag{28}$$

in which a_n represents undetermined coefficients. Then

$$\int_0^L \left(\frac{d\phi}{dx} \right)^2 dx = \frac{\pi^2}{2\,L} \sum_{n=1}^{\infty} n^2\, a_n^2 \tag{29}$$

and

$$\int_0^L \left(\frac{d^2\phi}{dx^2} \right)^2 dx = \frac{\pi^4}{2\,L^3} \sum_{n=1}^{\infty} n^4\, a_n^2 \tag{30}$$

Substituting these values in Eqs. 25 and 27 and equating $W_e = W$, one arrives at

$$M_{cr} = E\, \frac{I\,c\,\dfrac{\pi^2}{L^2} \displaystyle\sum_{n=1}^{\infty} n^4\, a_n^2 + \dfrac{C}{c} \displaystyle\sum_{n=1}^{\infty} n^2\, a_n^2}{\displaystyle\sum_{n=1}^{\infty} n^2\, a_n^2} \tag{31}$$

All possible values of a_n^2 are fundamentally positive quantities. Consequently, the smallest value of M_{cr} corresponds to $n = 1$. It is thus shown that a laterally restrained beam buckles in a single half wave; in addition, in the particular case of pure bending, Eq. 1 is seen to be the exact expression for the shape of the beam.

Therefore, with $n = 1$,

$$M_{cr} = E \left(c\,\frac{\pi^2}{L^2}\,I + \frac{C}{c} \right) \tag{32a}$$

Since, for a rectangular beam, $c = \dfrac{h}{2}$,

$$M_{cr} = E \left(h\,\frac{\pi^2}{2\,L^2}\,I + \frac{2\,c}{h} \right) \tag{32b}$$

(*b*) *Center Load.*—The expression for the strain energy is the same as in the previous case (Eq. 25).

The vertical displacement of the load P is obtained by the same reasoning as in the case of I-beams. Thus (see Eq. 19):

$$\Delta_1 = a^2 \frac{f - c}{2} \qquad (19)$$

$$\Delta_2 = - c \int_0^{L/2} \phi \frac{d^2\phi}{dx^2} x \, dx \qquad (33)$$

and

$$W = P \left(a^2 \frac{f - c}{2} - c \int_0^{L/2} \phi \frac{d^2\phi}{dx^2} x \, dx \right) \qquad (34)$$

From $W_\epsilon = W$, the following expression for the critical load is obtained:

$$P_{cr} = E \frac{\pi^2}{L} \frac{I c^2 \dfrac{\pi^2}{L^2} + C}{2f + c\left(\dfrac{\pi^2}{4} - 1\right)} \qquad (35a)$$

or, since for a rectangle, $c = \dfrac{h}{2}$,

$$P_{cr} = E \frac{\pi^2}{L} \frac{\left(\dfrac{\pi h}{2L}\right)^2 I + C}{2f + 0.5\, L\left(\dfrac{\pi^2}{4} - 1\right)} \qquad (35b)$$

It may be noted that both Eq. 32*a* and Eq. 35*a* also apply to cross sections other than rectangles, provided that the nature of the section is such that its total resistance to torsion is proportional to K only. This is generally true for cross sections that do not have transversely projecting parts (flanges, etc.).

I-Beams Horizontally Restrained Along Tension Flange

This case is realized for sheets or plates stiffened by projecting ribs of I-beam or T-beam shape and subject to bending of such nature that the sheet or plate is in tension. The sheet is then to be regarded as an integral part of the stiffener—that is, it is to be included in the determination of the moment of inertia I_2 of the tension flange. Whether or not it is also to be included in the determination of the torsional constant K depends upon the type of joint between stiffener and sheet. For joints acting rather in a hinge-like manner (that is, allowing rotation of the stiffeners with respect to the sheet), K should be taken for the stiffener only. The same is true for rather thin sheets (as compared with the wall thickness of the stiffener), since in this case the sheet is likely to bend slightly out of its plane in the immediate vicinity of the joint rather than to twist monolithically with the stiffener.

(*a*) *Pure Bending.*—It is seen from Fig. 5 that, in this case, for small angles ϕ,

$$y = c_2\,\phi \qquad (36)$$

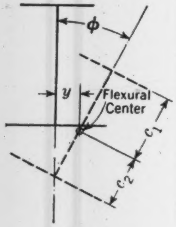

FIG. 5

Substituting Eq. 36 in Eq. 5 and remembering that

$$c_2 = h\,\frac{I_1}{I} \qquad (37)$$

the strain energy (after introducing the corresponding values for the integrals) becomes

$$W_\epsilon = E\,\frac{\pi^2 h^2}{4\,L}\left(I_1\,\frac{\pi^2}{L^2} + \frac{C}{h^2}\right)a^2 \qquad (38)$$

On the other hand, substituting Eq. 36 in Eq. 11 for β, one arrives at

$$W = \frac{h\,M}{4}\,\frac{\pi^2}{L}\,a^2 \qquad (39)$$

Again, making $W_\epsilon = W$, it follows that the critical moment

$$M_{cr} = E\,h\left(I_1\,\frac{\pi^2}{L^2} + \frac{C}{h^2}\right) \qquad (40)$$

Eq. 40 is seen to be independent of I_2, because the tension flange is not subject to any horizontal displacement and the position of the external forces (that is, M) is in no way connected with the position of the flexural center. For this reason Eq. 40 applies to symmetrical as well as to unsymmetrical **I**-beams.

(*b*) *Center Load.*—Eq. 38 for the strain energy remains the same as in the previous case. The vertical displacement of the load, with $y = c_2\,\phi$, becomes

$$\Delta = \Delta_1 + \Delta_2 = a^2\,\frac{f - c_2}{2} - c_2\int_0^{L/2} \phi\,\frac{d^2\phi}{dx^2}\,x\,dx \qquad (41)$$

and the work of the external force P

$$W = \frac{P}{2\,I}\left[f\,I + \frac{h\,I_1}{2}\left(\frac{\pi^2}{4} - 1\right)\right]a^2 \qquad (42)$$

From $W_\epsilon = W$

$$P_{cr} = E\,I\,\frac{\pi^2 h^2}{2\,L}\,\frac{I_1\,\frac{\pi^2}{L^2} + \frac{C}{h^2}}{f\,I + \frac{h\,I_1}{2}\left(\frac{\pi^2}{4} - 1\right)} \qquad (43a)$$

and for the special case of $I_1 = I_2 = I_0, f = \frac{h}{2}$,

$$P_{cr} = 2\,E\,h\,\frac{\pi^2}{L}\,\frac{I_0\,\frac{\pi^2}{L^2} + \frac{C}{h^2}}{\frac{\pi^2}{4} + 1} \qquad (43b)$$

TRUSSES AND I-BEAMS WITH THIN WEBS

These elements require special consideration for the following reason: In general the critical load depends upon the horizontal flexural rigidity and upon the torsional rigidity of the beam. For ordinary beams with thick webs the torsional constant may be determined from well-known formulas.[7] These constants have been derived on the assumption that the shape of the cross section does not change during torsion, or, in other words, that all component parts of the cross section are rotated through the same angle. This is not the case for latticed trusses, however (see Fig. 6(*a*)), and for beams with thin webs (see Fig. 6(*b*)). In such elements the lateral rigidity of the web, in many cases, is so slight that it bends out of its plane when the beam becomes unstable. For this reason the angle of rotation α_1 of the chords or flanges is seen to be less than the angle of rotation α_2 of the line AB in Fig. 6(*c*). Consequently the actual torsional rigidity of such elements will be less than that obtained from a formal application of the usual formulas for the torsional constant *K*. The determination of the actual torsional resistance of such members would require highly involved computations in each particular case and thus is beyond the scope of this paper.

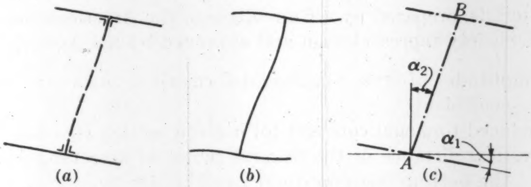

FIG. 6

However, for beams of this type, if *K'* is computed on the basis of the usual formulas (that is, without considering the distortion of the cross section) it will be found that the contribution to the critical load of the lateral flexural rigidity *E I* is usually far in excess of the contribution of the torsional rigidity *G K* to the critical load. Since the actual torsional constant *K* for beams of this type usually is considerably less than *K'* derived by formula, it seems advisable to determine the critical load of such beams by disregarding *K* entirely (that is, by assuming $K = 0$). The value thus obtained will be on the conservative side. On the other hand, if the effect of distorting the cross section were disregarded (that is, if *K'*, determined by formula, were used instead of the unknown actual *K*), the computed critical loads would be decidedly in excess of the actual loads. It is believed, therefore, that the first of these procedures (that is, assuming $K = 0$ for beams of this type) is by far preferable in current design practice.

CONCLUSION

In order to facilitate the use of the results of this investigation for beams with very small torsional constants, the formulas presented in this paper are assembled for reference in Appendix II.

APPENDIX I

NOTATION

The following letter symbols, adopted for use in this paper, conform essentially to Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials, prepared by a Committee of the American Standards Association with Society representation and approved by the Association in 1932.[8]

a = amplitude of the angular deformation: a_n = an undetermined coefficient;
C = reduced torsional constant for a given section (see Eq. 7);
c = vertical distance of the flexural center of a rectangular beam from the bottom (tension edge) (see Fig. 1):
    c_1 = distance from the center of the compression flange;
    c_2 = distance from the center of the tension flange (Fig. 2);
E = Young's modulus;
f = vertical distance from the bottom flange to the point of application of P;
G = shear modulus (Eq. 6);
h = effective height of section, between centers of flanges $(c_1 + c_2)$;
I = total moment of inertia $(I_1 + I_2)$ of a cross section with respect to the vertical axis of symmetry, particularly for I-beams (the moment of inertia of the web about its vertical axis is ignored):
    I_1 = inertia moment of the compression flange about the same axis;
    I_2 = inertia moment of the tension flange about the same axis;
K = torsional constant for a given cross section: K' = a computed constant as compared with (K) an actual constant;
L = span length, between supports:
    $\Delta' L$ = longitudinal displacement of the top (tension) flange, at the support;
    $\Delta'' L$ = longitudinal displacement of the bottom (compression) flange, at the support;
M = vertical bending moment:
    M_{cr} = critical moment;
    M_y = lateral component of M;
P = a concentrated external load (Eq. 5);
W = work of external forces: W_e = strain energy;

---

[8] ASA—Z10a—1932.

x = a longitudinal ordinate (see Fig. 1);
y = deflection, horizontal bending displacement (see Fig. 1);
α = angle of rotation:
  α_1 = rotation of the chords or flanges of an I-beam;
  α_2 = rotation of the web (Fig. 6);
β = vertical angle of rotation of the end section (Fig. 3);
Δ = total linear deformation (see also ΔL):
  Δ_1 = relative displacement of the point of application of the load P, with respect to the flexural center;
  Δ_2 = relative displacement of the flexural center with respect to the support, caused by the horizontal curvature of the longitudinal axis of the beams through the flexural center;
μ = Poisson's ratio;
ϕ = total angular deformation (Fig. 1): ϕ_c = angle ϕ at the center of the span.

APPENDIX II

Design Equations

The design equations discussed in some detail in the paper are Eqs. 14, 22, 32, 35, 40, and 43. For beams with very small torsional rigidity, in particular for open web trusses and thin wall beams, assuming in this case $K = 0$, one obtains the following simplified expressions—

Unsymmetrical I-beams, pure bending, unrestrained:

$$M_{cr} = E\,h\,I_1 \frac{\pi^2}{L^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (44a)$$

Symmetrical I-beam, pure bending, unrestrained:

$$M_{cr} = E\,h\,I_0 \frac{\pi^2}{L^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (44b)$$

Unsymmetrical I-beam, center load, unrestrained:

$$P_{cr} = \frac{48\,\pi^2 E}{L^3\,(6 + \pi^2)} \left[(h\,I_1 - f\,I) + \sqrt{(h\,I_1 - f\,I)^2 + \frac{6 + \pi^2}{48}\,h^2\,\pi^2\,I_1\,I_2} \right] \ldots (45a)$$

Symmetrical I-beam, center load, $f = \frac{h}{2}$, unrestrained:

$$P_{cr} = E\,h\,I_0 \frac{\pi^3}{L^3} \sqrt{\frac{48}{6 + \pi^2}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (45b)$$

Unsymmetrical I-beam, pure bending, restrained:

$$M_{cr} = E\,h\,I_1 \frac{\pi^2}{L^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (46a)$$

Symmetrical I-beam, pure bending, restrained:

$$M_{cr} = E\,h\,I_0\,\frac{\pi^2}{L^2}\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46b)$$

Unsymmetrical I-beam, center load, restrained:

$$P_{cr} = E\,I\,\frac{\pi^3}{2\,L^3}\,h^2\,\frac{I_1\,\pi}{f\,I + \dfrac{h\,I_1}{2}\left(\dfrac{\pi^2}{4} - 1\right)}\ldots\ldots\ldots\ldots (47a)$$

Symmetrical I-beam, center load, $f = \dfrac{h}{2}$, restrained:

$$P_{cr} = E\,I\,\frac{\pi^3}{L^3}\,h\,\frac{2\,\pi}{\dfrac{\pi^2}{4} + 1}\ldots\ldots\ldots\ldots\ldots\ldots (47b)$$

The formal requirements for the use of these formulas are: For Eqs. 44 and 45*b*, $C \ll \dfrac{I}{4}\left(\dfrac{\pi\,h}{L}\right)^2$; for Eq. 45*a*, $C \ll \dfrac{I_1\,I_2}{I}\left(\dfrac{\pi\,h}{L}\right)^2$; and for Eqs. 46 and 47, $C \ll I_1\left(\dfrac{\pi\,h}{L}\right)^2$ ($\ll$ denotes "much less than").

As stated previously, in beams of this type, the actual value of K is generally unknown and it is only evident that $K < K'$. For this reason these formal requirements should be used with critical care as guides rather than as rigorously applicable criteria.

DISCUSSION

Robert K. Schrader,[9] **Jun. Am. Soc. C. E.**—Two types of loading commonly encountered in practice—(*a*) uniformly distributed load, and (*b*) two equal loads symmetrically located on the beam—lend themselves readily to analysis by the method presented in this paper. In his treatment of this problem, herein, the writer leaves the directions of the coordinate axes unchanged, but the origin is transferred to the center of the undistorted beam.

(*a*) *Uniformly Distributed Load.*—With the coordinate system thus transferred, the author's approximate expression for the angular deformation, Eq. 1, now becomes:

$$\phi = a \cos \frac{\pi x}{L} \qquad (48)$$

Eq. 5, for the strain energy W_e, remains unchanged except that the limits of integration now extend from $-\frac{L}{2}$ to $+\frac{L}{2}$. For uniformly distributed load the vertical bending moment M to be substituted in Eq. 8 is

$$M = \frac{q}{2}\left(\frac{L^2}{4} - x^2\right) \qquad (49a)$$

Consequently,

$$\left(\frac{d^2y}{dx^2}\right)^2 = \frac{q^2}{4\,E^2\,I^2}\left(\frac{L^4}{16} - \frac{L^2\,x^2}{2} + x^4\right)\phi^2 \qquad (49b)$$

Substitution of Eqs. 1 and 49*b* in the equation for the strain energy yields, for this case,

$$W_e = \frac{a^2}{4\,I}\left[\frac{q^2\,L^5\,(\pi^4 + 45)}{120\,\pi^4\,E} + \frac{\pi^4\,h^2\,I_1\,I_2\,E}{L^3} + \frac{\pi^2\,C\,E\,I}{L}\right] \qquad (50)$$

The loss in potential energy, or the work done by the load, is equal to the magnitude of the load multiplied by the distance the load falls as the beam deflects laterally. This distance is again divided into two components, Δ_1 and Δ_2 (see Fig. 2). It is seen that for any section

$$\Delta_1 = (f - c_2)(1 - \cos\phi) \qquad (51a)$$

Substituting c_2 from Eq. 3*b*, expanding $\cos\phi$ in a power series in ϕ, and neglecting all terms beyond the second in this expansion, one obtains

$$\Delta_1 = \frac{(f\,I - h\,I_1)}{2\,I}\,\phi^2 \qquad (51b)$$

From Fig. 7 it is seen that

$$\Delta_2 = \Delta'_2 - \Delta''_2 \qquad (52)$$

in which Δ'_2 is the vertical displacement of the flexural center at midspan due to lateral displacement, and Δ''_2 is the difference between this displacement and that of a section at a distance $\bar{x}$ from the origin. From the geometry of the problem the magnitudes of these two components are given by the following expressions:

---

[9] 2d Lt., Air Corps, U. S. Army, Oak Park, Ill.

$$\Delta'_2 = \int_0^{L/2} \phi \frac{d^2y}{dx^2}\left(\frac{L}{2} - x\right) dx \ldots\ldots\ldots\ldots\ldots (53a)$$

and

$$\Delta''_2 = \int_0^{\bar{x}} \phi \frac{d^2y}{dx^2}(\bar{x} - x)\, dx \ldots\ldots\ldots\ldots\ldots (53b)$$

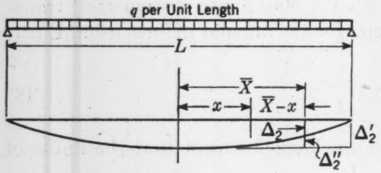

FIG. 7

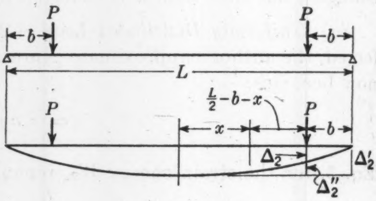

FIG. 8

The total work done by the uniformly distributed load, q, is

$$W = \int_{-L/2}^{L/2} q\,(\Delta_1 + \Delta_2)\, dx \ldots\ldots\ldots\ldots\ldots (54a)$$

By substitution of the expressions for Δ_1 and Δ_2 given in Eqs. 51 and 52 and by evaluation of the integrals, the total work becomes

$$W = \frac{a^2}{4\,I}\left[q\,L\,(f\,I - h\,I_1) + \frac{q^2\,L^5\,(\pi^4 + 45)}{60\,\pi^4\,E}\right] \ldots\ldots\ldots (54b)$$

The critical load is obtained by equating W_e from Eq. 50 to W from Eq. 54b, which results in

$$q_{cr} = \frac{60\,\pi^4\,E}{L^4\,(\pi^4 + 45)}\left[(h\,I_1 - f\,I) + \sqrt{(h\,I_1 - f\,I)^2 + \frac{\pi^4 + 45}{30}\left(h^2\,I_1\,I_2 + \frac{C\,I\,L^2}{\pi^2}\right)}\right] \ldots\ldots\ldots (55)$$

For the special case of a symmetrical I-beam loaded along its gravity axis, the results from Eq. 55 coincide with those obtained by Professor Timoshenko for this case.[10]

(b) *Two Equal Loads, Symmetrically Placed.*—Considering the right half of the beam shown in Fig. 8, it is seen that, from $x = 0$ to $x = (L/2 - b)$, the bending moment is

$$M = P\,b \ldots\ldots\ldots\ldots\ldots\ldots (56a)$$

and therefore, for this part of the beam,

$$\left(\frac{d^2y_1}{dx^2}\right)^2 = \frac{P^2\,b^2}{E^2\,I^2}\,\phi^2 \ldots\ldots\ldots\ldots\ldots\ldots (56b)$$

---

[10] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York, N. Y., Table 23, p. 268.

From $x = (L/2 - b)$ to $x = L/2$ the moment is

$$M = P\left(\frac{L}{2} - x\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (57a)$$

and therefore,

$$\left(\frac{d^2 y_2}{dx^2}\right)^2 = \frac{P^2}{E^2 I^2}\left(\frac{L^2}{4} - L\,x + x^2\right)\phi^2 \ldots\ldots\ldots\ldots (57b)$$

The strain energy of one half of the beam is then obtained from

$$W_e = \frac{E}{2}\left[I\int_0^{(L/2-b)}\left(\frac{d^2 y_1}{dx^2}\right)^2 dx + I\int_{(L/2-b)}^{L/2}\left(\frac{d^2 y_2}{dx^2}\right)^2 dx\right.$$
$$\left. + h^2\frac{I_1\,I_2}{I}\int_0^{L/2}\left(\frac{d^2\phi}{dx^2}\right)^2 dx + C\int_0^{L/2}\left(\frac{d\phi}{dx}\right)^2 dx\right] \ldots\ldots (58a)$$

Substitution of Eqs. 56*b* and 57*b* and evaluation of the integrals yield

$$W_e = \frac{a^2}{8\,I}\left[\frac{P^2}{E}\left(b^2 L - \frac{4\,b^3}{3} - \frac{b\,L^2}{\pi^2}\cos\frac{2\,\pi\,b}{L} + \frac{L^3}{2\,\pi^3}\sin\frac{2\,\pi\,b}{L}\right)\right.$$
$$\left. + \frac{\pi^4\,h^2\,I_1\,I_2}{L^3} + \frac{\pi^2\,C\,E\,I}{L}\right] \ldots\ldots\ldots\ldots\ldots\ldots (58b)$$

To find the work done by each of the two forces P, the distance the load falls will be divided into two components Δ_1 and Δ_2 as before, and again

$$\Delta_1 = \frac{(f\,I - h\,I_1)}{2\,I}\,\phi^2_b = \frac{(f\,I - h\,I_1)}{2\,I}\,a^2\sin^2\frac{\pi\,b}{L} \ldots\ldots\ldots (59)$$

in which ϕ_b is the angular displacement of the load. From Fig. 8 it is seen that, in analogy with Eq. 52, $\Delta_2 = \Delta'_2 - \Delta''_2$, as before, in which Δ'_2 is again the vertical displacement of the flexural center at midspan, and Δ''_2 is now the difference between this displacement and that at the loaded section. Consequently,

$$\Delta'_2 = \int_0^{(L/2-b)}\phi\,\frac{d^2 y_1}{dx^2}\left(\frac{L}{2} - x\right)dx + \int_{(L/2-b)}^{L/2}\phi\,\frac{d^2 y_2}{dx^2}\left(\frac{L}{2} - x\right)dx \ldots (60a)$$

and

$$\Delta''_2 = \int_0^{(L/2-b)}\phi\,\frac{d^2 y_1}{dx^2}\left(\frac{L}{2} - b - x\right)dx \ldots\ldots\ldots\ldots (60b)$$

The work done by P is then

$$W = P\,(\Delta_1 + \Delta_2) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (61a)$$

By substitution of Eqs. 59 and 60, and by evaluation of the integrals, the work becomes

$$W = \frac{a^4}{8\,I}\left[4\,P\,(f\,I - h\,I_1)\sin^2\frac{\pi\,b}{L}\right.$$
$$\left. + \frac{P^2}{E}\left(2\,b^2 L - \frac{8\,b^3}{3} - \frac{2\,b\,L^2}{\pi^2}\cos\frac{2\,\pi\,b}{L} + \frac{L^3}{\pi^3}\sin\frac{2\,\pi\,b}{L}\right)\right] \ldots (61b)$$

The critical load is obtained by equating W_e from Eq. 58*b* to W from Eq. 61*b*, which results in

$$P_{cr} = A \frac{E}{L^3}\left[(h\,I_1 - f\,I) + \sqrt{(h\,I_1 - f\,I)^2 + B\,h^2\,I_1\,I_2 + D\,C\,I\,L^2}\right] \;..(62)$$

In Eq. 62, A, B, and D are numerical coefficients the values of which, for different ratios of b/L, are given in Table 1.

TABLE 1.—NUMERICAL COEFFICIENTS FOR THE SOLUTION OF EQ. 62

Coefficients	Ratios b/L									
	0.05	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50
A	19.59	19.20	18.64	18.00	17.30	16.62	16.00	15.51	15.09	14.93
B	101.6	26.57	12.68	7.84	5.63	4.53	3.83	3.48	3.31	3.27
D	10.3	2.69	1.28	0.794	0.570	0.448	0.369	0.353	0.335	0.331

It may be ascertained easily that, for $b/L = 0.5$, the value $2\,P_{cr}$ of this analysis is identical with that for a concentrated center load obtained by the author. Also, for $b/L = 0.05$, almost the entire length of the beam is subject to pure bending. The critical moment so computed differs from that obtained by the author for pure bending of the entire beam by only 0.1%.

Acknowledgment.—This discussion is based on a thesis prepared under the supervision of the author and submitted to Cornell University, at Ithaca, N. Y., in 1941 in partial fulfilment of the requirements for the degree of Master of Civil Engineering.

H. N. HILL,[11] ASSOC. M. AM. SOC. C. E.—In 1937 the writer had occasion to solve the problem of the lateral buckling of an unsymmetrical I-beam subjected to pure bending, and derived an expression which differs somewhat from that determined by the author. The writer's solution can be expressed in the notation of the paper, if an additional term is introduced—"e," which is defined as the distance from the shear (or flexural) center to the centroid of the section. The centroid will lie between the shear center and the narrow flange. The term "e" will have a positive sign if the wide flange is in compression, and a negative sign if the narrow flange is in compression.

Using the disposition of axes as shown in Fig. 2 of the paper, the differential equations of equilibrium for lateral bending and twisting can be written: $E\,I\,\frac{d^2y}{dx^2} = -\,M\,\phi$ (see Eq. 8), and

$$G\,K\,\frac{d\phi}{dx} - E\,(I_1\,c^2_1 + I_2\,c^2_2)\,\frac{d^3\phi}{dx^3} = M\,\frac{d}{dx}\,(y - 2\,e\,\phi) \;.......(63)$$

In Eq. 63 the expression for the twisting moment is only approximately correct. It is applicable for unsymmetrical I-sections of the kind dealt with in this paper, and in which the two flange areas do not differ greatly. The unsymmetrical

---

I-beams commonly encountered in structural fields are of this nature. A more exact expression for the twisting moment may be obtained by summing up the twisting moments produced by the longitudinal stress on each unit differential area of the cross section. The expression may be derived as follows, considering the z-axis as coinciding with the center line of the web, with the origin at the shear center, and assuming that the flanges are narrow compared to the depth of the beam:

$$M_T = \int_A \frac{M}{I_Y} (z - e)\, dA \left(\frac{dy}{dx} - z \frac{d\phi}{dx} \right) z \ldots\ldots\ldots\ldots (64)$$

in which I_Y = moment of inertia about the principal axis normal to the web. Expanding:

$$M_T = \frac{M}{I_Y} \left[\frac{dy}{dx} \left(\int_A z^2\, dA - e \int_A z\, dA \right) - \frac{d\phi}{dx} \left(\int_A z^3\, dA - e \int_A z^2\, dA \right) \right] \ldots (65)$$

in which

$$\int_A z\, dA = e\, A \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (66a)$$

$$\int_A z^2\, dA = I_Y + e^2 A \ldots\ldots\ldots\ldots\ldots\ldots\ldots (66b)$$

and

$$\int_A z^3\, dA = Z_Y + 3\, e\, I_Y + e^3 A \ldots\ldots\ldots\ldots\ldots (66c)$$

In Eq. 66c, Z_Y is the third moment of the area about the principal axis normal to the web. Therefore,

$$M_T = M \frac{d}{dx} \left[y - \left(2\, e + \frac{Z_Y}{I_Y} \right) \phi \right] \ldots\ldots\ldots\ldots\ldots (67)$$

For an I-beam in which the two flange areas are not greatly different, it is evident that the centroid will not vary greatly from a point at half the depth, and the term $\frac{Z_Y}{I_Y}$ will be very small. The areas of the two flanges of an unsymmetrical I-beam may be the same and yet their lateral stiffnesses may differ greatly.

Differentiating Eq. 63 and substituting for $\frac{d^2y}{dx^2}$ its value from Eq. 8 results in the differential equation

$$\frac{d^4\phi}{dx^4} - \frac{G\, K + 2\, M\, e}{E\, (I_1\, c_1^2 + I_2\, c_2^2)} \frac{d^2\phi}{dx^2} - \frac{M^2}{E^2\, I\, (I_1\, c_1^2 + I_2\, c_2^2)} \phi = 0 \ldots\ldots (68)$$

The solution of this fourth-order linear differential equation, with constants determined from the boundary conditions ($\phi = 0$, $\frac{d^2\phi}{dx^2} = 0$ when $x = 0$ and $x = L$), results in the trigonometric equation

$$\sin L \sqrt{-\frac{G\, K + 2\, M\, e}{2\, E\, (I_1 c_1^2 + I_2 c_2^2)} + \sqrt{\frac{(G\, K + 2\, M\, e)^2}{4\, E^2\, (I_1 c_1^2 + I_2 c_2^2)^2} + \frac{M^2}{E^2\, I\, (I_1 c_1^2 + I_2 c_2^2)}}} = 0 \ldots (69)$$

The smallest non-trivial root of Eq. 69, solved for the bending moment M, gives, for the critical bending moment,

$$M_{cr} = \frac{\pi^2 E\, I}{L^2} \left(\sqrt{\frac{L^2 G\, K}{\pi^2 E\, I} + \frac{I_1 I_2}{I^2} h^2 + e^2} + e \right) \qquad (70)$$

Expressed in the form of Eq. 14*a*, Eq. 70 would read

$$M_{cr} = E\, h \frac{\pi^2}{2\, L^2} \left(I \frac{2\, e}{h} + \sqrt{4\, I_1 I_2 + I^2 \frac{4\, e^2}{h^2} + 4\, C\, I \frac{L^2}{\pi^2 h^2}} \right) \qquad (71)$$

For the case of a symmetrical I-beam ($I_1 = I_2 = I_0$, and $e = 0$), Eq. 71 reduces to Eq. 14*b*.

The difference between Eqs. 71 and 14*a* is largely in the inclusion of the term e in the former. In the author's solution, no account is taken of the location of the centroid of the cross section. The reason for this discrepancy between the two solutions apparently lies in the method used by the author for evaluating the work of the external forces (Eqs. 10, 11, and 13). Eq. 10 is correct only if the end sections, which rotate through an angle β, remain plane. Under the combined lateral bending and twisting, the end sections do not remain plane. That this is so can be seen from Eq. 11. The change in chord length of a longitudinal fiber varies as the square of the lateral deflection of that fiber at the middle of the span. Since this deflection varies linearly with the depth of the beam, the change in chord length cannot vary linearly with the depth.

To determine the work of the external moment, it is probably necessary to sum up the work done by the forces acting on each unit differential area of the cross section. This would involve the stress distribution on the section and consequently the location of the centroid.

GEORGE WINTER,[12] ESQ.—In connection with the general tendency toward higher working stresses and more slender members in engineering structures, problems of the stability of such members are becoming increasingly important and are given wide attention in engineering research. Since the first publication of the writer's paper in December, 1941, three articles on related topics have been published. Prof. J. N. Goodier[13,14] has given a comprehensive and, in many respects, fundamentally new treatment of stability problems involving the simultaneous occurrence of compression, bending, and twist. Mr. Hill[15] has investigated the buckling of unsymmetrical I-beams in pure bending—that is, the same problem which forms part of the writer's paper. Whereas the writer derived his equations by means of energy principles, Mr. Hill used differential equations for this purpose. His discussion of the writer's paper represents an abstract of his aforementioned article.[15]

For the case of pure bending, Mr. Hill derives Eq. 71 which, in form, differs from Eq. 14*a* for the same case. As Mr. Hill rightly points out, his equations are rigorously exact only if the centroid of the section is midway between the flanges. The same holds true for the writer's equation. This does not mean that these equations apply to symmetrical beams only. Although the areas of the flanges must be equal in this case, the $\frac{b}{t}$-ratios for the two flanges may be different (b = width, t = thickness). In many instances beams are so designed in structural practice, especially to avoid local crippling of the compression flange due to large $\frac{b}{t}$-ratios.

---

[14] "Flexural-Torsional Buckling of Bars of Open Section," by J. N. Goodier, *Bulletin No. 28*, *ibid.*, January, 1942.

[15] "The Lateral Instability of Unsymmetrical I-Beams," by H. N. Hill, *Journal of Aeronautical Sciences*, Vol. 9, No. 5, March, 1942.

The writer is gratified to find that, for the case of equal flange areas (the only one for which both equations are strictly exact), Mr. Hill's and his own expressions are identical. To demonstrate this fact let Fig. 9 represent an I-beam with a centroid C, a flexural center F, and a midpoint M. Then the distance e, introduced by Mr. Hill, is the distance from C to F. For equal flange areas the points C and M coincide. In this case, with the notation of the paper and Mr. Hill's rule of signs,

$$e = -\left(\frac{h}{2} - c\right) = \frac{h}{2}\,\frac{I_1 - I_2}{I} \ldots\ldots (72)$$

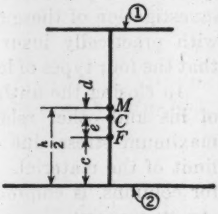

FIG. 9

Substitution of this expression in the second term of Eq. 71 gives:

$$I\,\frac{2\,e}{h} = I_1 - I_2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (73)$$

which is identical with the second term of Eq. 14*a*. Likewise, substituting the value of e in the fourth term of Eq. 71, and combining it with the third term, results in:

$$4\,I_1\,I_2 + I^2\,\frac{4\,e^2}{h^2} = I^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (74)$$

which, in turn, is identical with the corresponding term in Eq. 14*a*. For this case, then, Mr. Hill's and the writer's expressions are the same.

If C and M do not coincide, neither Mr. Hill's nor the writer's equations are strictly exact. In this case the difference between the two approaches is that Mr. Hill implicitly takes account of the distance d from the centroid C to the midpoint M. However, he neglects the quantity $\frac{Z_Y}{I_Y}$ (see Eq. 67). The magnitude of d is found from

$$d = \frac{h}{2}\,\frac{A_1 - A_2}{A_1 + A_2 + A_w} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (75)$$

in which A_1, A_2, and A_w are, respectively, the areas of the two flanges and of the web. It is easily seen that the quantity $\frac{Z_Y}{I_Y}$ is of the same order of magnitude as d. Therefore, little is gained in accuracy by taking account of d but neglecting $\frac{Z_Y}{I_Y}$. Except for the rare case of radically different values of A_1 and A_2, the quantity d is seen to be rather small as compared with $\frac{h}{2}$ or c. Therefore, the writer's simple Eq. 14*a* represents a close approximation even for the case in which the flange areas are different.

The practical advantage of the writer's work-energy method is that it provides a rather simple way of analyzing the stability of beams under transverse loading rather than only in pure bending. The writer's equations for pure bending and for center load are supplemented in Lieutenant Schrader's contribution by those for uniformly distributed loading and for two equal loads symmetrically located on the beam, derived by the writer's method. An investigation of these cases by means of differential equations would have met with practically insurmountable mathematical complexities. It is believed that the four types of loading analyzed cover the most important practical cases.

In closing the author wishes to draw attention to the fact that the results of his and other related investigations are directly applicable only if the maximum stress due to the critical load is smaller than the proportional limit of the material. This limitation, the same as that of the Euler formula for columns, is common to all calculations concerning the elastic stability of structures.

REDUCTION OF MINERAL CONTENT IN WATER WITH ORGANIC ZEOLITES

BY R. F. GOUDEY,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. JAMES M. MONTGOMERY, GEORGE L. DAVENPORT, JR., ROBERT SPURR WESTON, AND HARVEY F. LUDWIG AND RUSSELL G. LUDWIG.

SYNOPSIS

In general, the idea of deliberately reducing the mineral content in water has been limited to the field of boiler-feed water for steam generation purposes. Some incidental reduction in total solids in water has resulted when "temporary" hard waters have been softened with lime for domestic and industrial uses. Modern organic zeolites can now be used to secure an almost complete removal of solids even to the point of competing with distilled water. Already a number of high-pressure steam plants, ice plants, and a single instance of a large munitions plant, are using organic zeolites to produce water of a low mineral content for boiler-feed or rinsing purposes. The use of organic zeolites, while still expensive, has passed the academic stage. It has been recommended (1)[2] that the latest types of organic zeolites, called resinous exchangers, could be used most satisfactorily for processing and precipitate washing at drug and chemical plants.

It is possible to remove one or more of the positive and negative major ions from water including calcium, magnesium, sodium, alkalinity, sulfate, chloride, and nitrates. The full significance of this fact should be realized. The writer suggests that these newer methods of water treatment be considered in the following general instances:

(1) To reduce any major ion in water that exceeds United States Treasury Department Standards, such as sulfates, 250 ppm; chlorides, 250 ppm; and total solids, 1,000 ppm, or the present proposed limit of 500 ppm;

(2) To remove or alter objectionable ions in water for irrigation use with particular attention to lowering the sodium ratio and reducing total solids to within safe limits, even though calcium and magnesium salts can be kept high; and

---

NOTE.—Published in February, 1942, *Proceedings*.

[1] San. Engr., Bureau of Water Works and Supply, Los Angeles, Calif.

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (Appendix).

(3) To extend the applications in which undesirable waters can be modified for safe industrial use, particularly where relatively high costs can be tolerated.

These suggestions do not recommend the production of distilled water for all uses; but, by blending portions of water variously treated and, in some instances, the addition of compounds, there can be a selective modification of various ions in water to produce a final water satisfactory for the purposes intended. Such a development opens up many practical applications of far-reaching economic importance.

DEVELOPMENT OF ZEOLITES

Although the treatment of water with zeolites consists, for the most part, in exchanging calcium and magnesium for sodium, and regenerating the zeolites when exhausted with salt which results in a softer water, there is an actual increase in total solids because the equivalent sodium ions are heavier than the replaced ions. Nevertheless, the treatment by zeolites has been an important stepping stone to the development of more efficient exchange materials which can now be used to remove any of the major ions. The history in the development of zeolites, as applied to water treatment, started with the use of green inorganic sands (glauconite) as early as 1910. This material had an exchange ratio of sodium, for calcium and magnesium, based on about 2,800 grains of hardness (expressed as calcium carbonate) for a cubic foot of material. These natural zeolites were greatly improved during the following decade by processing which doubled the exchange capacity and increased the filtering rate. Common commercial products that were installed at Neville Island, Pennsylvania, in 1926 (2), and at the plant of the City of South Orange, N. J., in 1928 (3), marked the beginning of the use of zeolites for municipal softening.

The first artificial inorganic zeolites were produced as solutions of sodium silicate in 1906, and in the following year the reversible properties of such solutions were discovered. Artificial zeolites are manufactured either from sodium aluminate and sodium silicate to give a ratio of one part sodium oxide to 5.5 or 6.0 parts of silica or from aluminum sulfate and alkalized sodium silicate to give twice the aforementioned ratio. These materials are controlled to form a stiff solid gel or a gelatinous precipitate in liquor. The material is dried either naturally or artificially until it cracks into grains when sprinkled with water. Further control in processing determines the grain size, which is one of the factors in determining the capacity reaction and the loss of head through the filters. Modern inorganic zeolites, therefore, are referred to as "gel-type" zeolites. Their capacity varies from 9,000 to 12,500 grains of hardness removal as calcium carbonate. Most manufacturers guarantee 8,000 grains of hardness removed for each cubic foot of material, although this is not a fair basis for a guarantee as the capacity up to 12,500 grains of hardness removed is dependent on the amount of salt used for regeneration. The rate of filtration for natural zeolites is 5 to 8 gal per sq ft per min with a 40-min period of regeneration. Artificial zeolites require less rinsing than natural zeolites. Downward filtration may be used with all inorganic zeolites.

Salt consumption for regeneration theoretically should average 0.167 lb of salt for each 1,000 grains of hardness removed. The reaction, however, requires the presence of a salt excess and the actual regeneration dosage under the most advantageous conditions, such as municipal plants, varies from 0.33 to 0.4 lb per 1,000 grains of hardness removed. The amount of salt for regeneration at industrial plants is usually 0.4 to 0.5 lb per 1,000 grains of hardness removed. Even higher salt consumption is allowed for individual domestic units—namely 0.5 to 0.7 lb per 1,000 grains of hardness. The lowest figure for salt consumption requires either reuse of portions of the brine, which is a patented process, regeneration of the zeolite at about 85% capacity, or less, or utilization of longer periods of regeneration.

A large proportion of material used in industry includes solar dried commercial products manufactured at Yuma, Ariz., and Chicago, Ill. Processed material, not solar dried, is manufactured in New York, N. Y., and Chicago. More than forty municipal plants have been constructed since 1935 using zeolites for municipal water softening (4).

A process of adding lime has been developed to remove temporary hardness and to treat a part of the lime-softened water with sodium zeolite to zero hardness for the removal of permanent hardness followed by mixing the raw, lime-treated water and the zeolite-treated water to obtain any final residual hardness desired. Such plants have been located at Findlay, Ohio, and the Metropolitan Water District of Southern California (5).

Lime is the most efficient agent for softening calcium bicarbonate waters because the reaction drops out the lime added and the temporary hardness, except for the solubility value of calcium carbonate, which is usually 40 to 60 ppm. The use of excess lime may remove half this residual. Only zeolites can reduce the calcium and magnesium ions to practically zero. Magnesium bicarbonate hardness requires twice as much lime as calcium, and noncarbonate hardness requires the addition of both lime and soda ash. The sodium zeolites remove these substances with about twice the salt required by the stoichemical reaction, and the advantage of lime and soda ash over zeolites becomes a matter of studying costs of chemicals involved. Usually zeolite softening is cheaper than lime and soda ash when the ratio of noncarbonate hardness is 50% or more of the total hardness (4).

The disadvantages of the sodium zeolite softening are: First, it increases the sodium ratio; second, the sodium zeolite must be used at pH-values between 7.0 and 7.8 as there is disintegration at both higher and lower pH-values; and third, water having passed through a municipal zeolite plant containing a residual hardness and a high pH-value such as 9.0 will cause disintegration of zeolites at local industrial plants which must further treat such waters for complete removal of hardness. Sodium zeolite waters in boiler-feed installations are often treated with sulfuric acid and aerated to remove bicarbonate, but the total solids are slightly increased.

Organic Zeolites.—Following the work of B. A. Adams and E. L. Holmes (6) in 1935, significant progress has been made in the development of organic zeolites (1). Cation exchangers, or organic zeolites, can be operated either on a sodium or hydrogen cycle depending on whether they are regenerated by salt or mineral acid. Most commercial plants are using 1% sulfuric acid for regeneration purposes. The first four compounds were formerly called carbonaceous zeolites and the last compound is referred to as synthetic resin. Resins are carbonaceous compounds and so the word "organic zeolites" has been selected to cover both phases of development.

The second group of materials which have been recently developed includes the anion exchangers for negative ion removal.

In 1940, the writer presented (7) a short bibliography of the development of carbonaceous zeolites. A more complete bibliography is to be found in a later work by R. J. Myers, J. W. Eastes, and F. J. Myers (1). Artificial organic zeolites have now been developed that are highly condensed, very hard, resistant, and extremely insoluble, and which have properly sized grains with large inner surfaces, high reactivity, and extreme mechanical strength. These zeolites, which are basically either tannin formaldehyde, or m-phenylenediamine resins, have been developed from a great number of compounds. Organic zeolites are somewhat lighter than inorganic zeolites and swell more without rupturing the internal lattice, even to the extent of increasing their size 25% before regeneration. After regeneration the organic zeolites return to normal size. This normal swelling and contracting is probably due to the difference in the size of molecules being exchanged. One third more freeboard for backwashing is required because the material is lighter.

Organic zeolites are installed in filters made acid or alkali resistant with an upward flow rate of 10 gal per sq ft per min with a backwash of 1 to 2 gal per sq ft per min and a rinse of 2 to 3 gal per sq ft per min. The capacity of hydrogen zeolite is proportional to the amount of acid or salt used for regeneration and is proportionately higher for increased capacities. Ordinarily, 0.3 lb of sulfuric acid per 1,000 grains of hardness or its equivalent removed is considered the most efficient method of operation. This represents a removal rate of about 8,000 grains of hardness per cubic foot of material.

In sodium silicate zeolites, the salt ratio is twice the theoretical amount required under the most favorable conditions of operation. Until recently the hydrogen zeolites required 0.292 lb of sulfuric acid per 1,000 grains of hardness removed (7) at a removal rate of 8,550 grains of hardness extracted for each cubic foot of material. This amount of acid is 2.08 times that which is theoretically required. No experiments have yet been published to establish the minimum acid requirements. The writer has used rates as low as 0.225 lb of sulfuric acid per 1,000 grains of hardness removed when operating on calcium only. This is 1.6 times the theoretical amount. That some excess acid must be added is obvious; yet the report of the increased chemical efficiency of resin exchangers used on a sodium cycle as compared with the sodium silicate zeolites indicates that considerably less acid may be required when resin exchangers are operated on a hydrogen cycle and particularly where sodium is high. For purposes of this paper and since the sulfuric acid requirement for treatment is the principal factor, an arbitrary figure of 0.2 lb of sulfuric acid per 1,000 grains of ions removed and expressed as calcium carbonate will be assumed.

Water that has passed through an organic cation exchanger becomes acid and the bicarbonates are converted to carbonic acid gas. The latter can be removed by aeration; hence the cation exchangers remove not only calcium, magnesium, and sodium, but also carbonates and bicarbonates.

The anion or negative ion exchangers have been developed somewhat more slowly. The first exchangers "leaked" and apparently the lattice structure became easily ruptured. Likewise, there was a tendency for the material to go into solution. The present anion exchangers, however, are extremely efficient. They are acid and alkali resistant, have a capacity of 29,800 grains per cubic foot of hardness removed, rinse with about one half the water used formerly, and give twice the filter runs. Regeneration with 1% sodium hydroxide or soda ash is used.

Organic zeolites exchange positive ions with hydrogen when mineral acids are used for regeneration. The exchange is probably on the phenolic hydroxyl group. The equations for initial and final stages are shown in Table 1.

TABLE 1.—TYPICAL EXCHANGE REACTIONS

No.	(a) CATION REACTIONS			(b). ANION REACTION		
	Hydrogen cycle	Sodium cycle	Magnesium cycle	Hydroxyl cycle	Carbon dioxide cycle	Chloride cycle
	H_2Z	Na_2Z	Mg Z	$Z(OH)_2$	Z CO_3	Z Cl_2

3	2 H Cl	2 Na Cl	Mg Cl_2	2 H_2O		

The removal of negative ions may be due strictly to adsorption or exchange, but for all practical purposes the hydroxide ion behaves parallel with the hydrogen ion and water treated by both methods. The writer found that chlorine replaced sulfates after the hydroxide is exhausted (7). In an experiment of passing 90 gal of Los Angeles (Calif.) aqueduct water through 277 g of a cation exchanger (7) the hydrogen zeolite became successively a sodium and a magnesium zeolite as the capacity to remove sodium and magnesium was reached. This means that hydrogen zeolites may be used to remove calcium only or calcium and magnesium together. Also, 100 gal of cation-treated water without aeration was passed through 333 g of an anion exchanger, and alkalinity, chlorides, and sulfates were removed in the same order as sodium, magnesium, and calcium. The alkalinity and chlorides exchanged successively with chlorides, finally being replaced with sulfates. This indicates that as ions sulfates can be removed more economically than chlorides. The equations in Table 1(*b*) indicate the initial and final stages of the negative ion reactions.

Regeneration of cation and anion exchangers follows the reactions:
Cation regeneration—

$$\left.\begin{matrix}\mathrm{Ca}\\ \mathrm{Mg}\\ \mathrm{Na_2}\end{matrix}\right\}\mathrm{Z} + \mathrm{H_2SO_4} = \mathrm{H_2Z} + \left.\begin{matrix}\mathrm{Ca}\\ \mathrm{Mg}\\ \mathrm{Na_2}\end{matrix}\right\}\mathrm{SO_4} \ldots\ldots\ldots\ldots\ldots (1)$$

anion regeneration—

$$\mathrm{Zx}\left\{\begin{matrix}\mathrm{Cl}\\ \mathrm{SO_4}\\ \mathrm{H\,CO_3}\end{matrix}\right. + 2\,\mathrm{Na\,OH} = \mathrm{Zx\,OH} + \mathrm{Na_2}\left\{\begin{matrix}\mathrm{Cl_2}\\ \mathrm{SO_4}\\ \mathrm{(H\,CO_3)_2}\end{matrix}\right. \ldots\ldots\ldots (2)$$

CARBONACEOUS ZEOLITES VERSUS SODIUM ZEOLITES

There is a growing tendency to use carbonaceous zeolites in place of sodium zeolites whether artificial or natural, for the reason that the sodium zeolites require narrow operating limits such as a pH-value from 7.0 to 7.8 beyond which zone there is softening of the structure with subsequent loss of silica. There is very little addition of silica to treated water within safe operating limits. At most small plants, however, the pH-variation is not subject to rigid control and there is, as stated, a tendency to favor a zeolite that is acid and alkali resistant. There are a number of installations using carbonaceous zeolites on a sodium cycle. One of the more recent developments has been the combined use of two carbonaceous zeolite filters (see Fig. 1), one operating with 50% of water on a sodium cycle and the other operating on the other 50% of the water supply on a hydrogen cycle with subsequent mixing of the two waters. There are a number of installations where carbonaceous zeolite is used on a sodium cycle followed by acid treatment to remove alkalinity and thereafter to degasify. This treatment, however, increases the total solids rather than decreases them, although it will produce a water low in hardness and alkalinity.

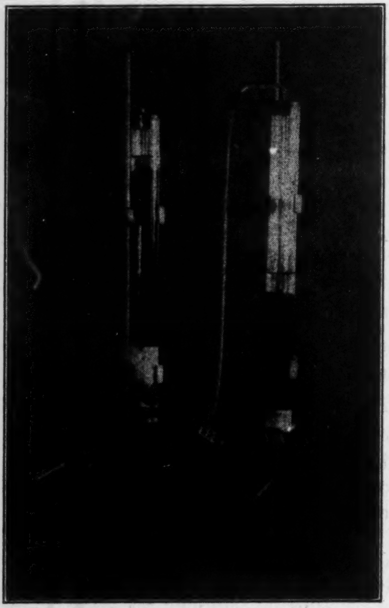

FIG. 1.—LABORATORY CARBONACEOUS ZEOLITE FILTERS

REDUCTION OF SOLIDS BY EVAPORATORS

In the high-pressure steam plant boiler-feed water field, evaporators have been designed to reduce total solids. With appropriate facilities (including separators so that water can be produced having 4 ppm, or less) total solids and the remaining ions are approximately proportional to the ratio of ions originally present. The first cost is relatively high—namely, about $100,000 per million gal capacity. Operation cost is that of distillation, which is about $2,000 per million gal. Plants that have heat exchange facilities allow practically nothing for the cost of operating evaporators. This process is too limited for general application; yet, where boiler make-up is high, evaporators would be extravagant and hydrogen zeolites offer the most economical treatment.

COST

Layouts for filters using sodium zeolites have been fairly well established. Municipal zeolite units run from $25,000 to $35,000 per million gal capacity, although the 70-million gal unit of the Metropolitan Water District of Southern California cost $5,000 per million gal. Treatment plants using the hydrogen cycle require greater tank depth but considerably less area and the equipment must be made acid proof. However, there should not be much difference in the final first cost of plants for equivalent treatment capacity. For the removal of alkalinity by aeration, additional equipment is required. Anion exchangers operate at more than twice the rate as cation exchangers so that the cost of filter assemblies is less than that of the corresponding cation exchanger for the same total flow.

The filtering material of exchangers is naturally a major item of expense and the cost of filtering material in any particular case is based on the quantities used. Freight for material shipped cross-country is a large part of the cost where large quantities cannot be manufactured near the points of use. Roughly, the current prices for sodium zeolite in large quantities average $4.50 per cu ft, organic zeolites on the hydrogen cycle at $9 per cu ft, and organic zeolites on the hydroxyl cycle at $36 per cu ft. These prices, while somewhat disconcerting at first glance, are certain to drop downward as use and production increase. From the standpoint of ease in manufacture, there is no reason why ultimately the prices for hydrogen and hydroxyl zeolites should not approach that of sodium zeolites. The royalty fee for hydrogen zeolites is $1 per cu ft, whereas hydroxyl zeolite is $5 per cu ft. Since the foregoing cost range parallels the relative efficiency of the materials involved so far as filtering rate and volume of material required are concerned, the cost of equivalent materials on a million gallon basis of water treated in any new moderately sized plant should be about the same as that now allowed for sodium zeolites. On the basis of present prices, however, the capital investment for moderately sized plants to remove various combinations of ions on a million gallon basis is as shown in Table 2. Obviously, smaller plants might cost 50% more, but the relative ratio of the costs between the various processes is probably the same as given in Table 2. From the standpoint of initial cost, there appears to be no real obstacle to a rather wide application for the newer processes. The data in Table 2 are based on removing ions to practically zero values. In many instances only a part of the water would be completely treated to be mixed with that ratio of raw water necessary to produce allowable values. If only one third of the water were to be treated, the cost per million gallons per day capacity would be one third of that indicated in Table 2.

TABLE 2.—RELATIVE COMPARISON OF INSTALLATION COSTS, IN DOLLARS PER MILLION GALLONS PER DAY CAPACITY, FOR VARIOUS COMBINATION REMOVALS

Description	ION EXCHANGE OR REMOVAL				
	Ca and Mg[a]	+Na	+Alkalinity	+Cl +SO_4	+Cl +SO_4[b]
First cost, thousand dollars per million gallons	35	50	53	70	100
Percentage of total solids removed	30[c]	<50	75[d]	99	99
Cost, in dollars per additional percentage of removal	1,160	750	120	680	1,000

[a] Sodium zeolite. [b] By evaporator. [c] 15% to 40%. [d] 65% to 90%.

Operation costs, however, are certain to be high in difficult cases. No general rule can be given owing to wide discrepancies in local prices of sulfuric acid and caustic soda. In July, 1941, the New York price for salt was $13.70 a ton; yet at the plant of the Metropolitan Water District of Southern California, the delivered price at the same time was $4.30 to $4.70 per ton. Sulfuric acid, although quoted in New York at $16.50 a ton, has been known to be delivered in large quantities at $11 a ton. Sodium hydroxide, quoted in New York at $46 a ton, can be delivered as low as $20 a ton at certain locations. In any particular case it would be necessary to calculate the chemical cost with amounts to be used and the cost of delivered chemicals. The amount of acid should be based on 0.2 lb of sulfuric acid per 1,000 grains of ions removed, the latter being expressed in terms of calcium carbonate, and 0.165 lb of sodium hydroxide for 1,000 grains of ions (as calcium carbonate) removed.

PRACTICAL APPLICATIONS

Waters high in bicarbonates lend themselves to high reductions in total solids through cation ion exchanges which, after aeration and mixed with raw waters, are not acid and may not require treatment by anion exchangers. The Los Angeles aqueduct supply is an example of such a water. Waters high in sulfates and chlorides usually require the addition of an alkali to produce a noncorrosive water if both cations and anions are removed in large amounts. The Colorado River water illustrates this type of water. With no thought of recommending the following schemes of treatment, but using them only to illustrate the complexity of reactions and wide variation in costs involved, illustrations follow as to how to produce water with a hardness of 85 ppm, a sodium ratio below 50%, and a sulfate content under 250 ppm from the two types of waters mentioned.

Case 1. Los Angeles Aqueduct.—In the Los Angeles Aqueduct (see Table 3) only cation treatment is necessary on 23% of the flow which, after aeration, is mixed with 77% of the untreated water. The acidity produced by the calcium, magnesium, and sodium reduction is neutralized by the alkalinity of the mixing water. This treatment requires a sulfuric acid dose of 550 lb per million gal on a chemical cost of \$3.00 to \$4.55 per million gal, which is relatively low.

It should be observed that were lime to be used to produce such a water, the sodium ratio would exceed an allowable 50%, reaching 53%.

From the standpoint of first cost, this type of treatment for this water is by far the most economical because it would be designed for only 23% of the total flow.

TABLE 3.—EFFECT OF MINERAL ADJUSTMENT
(Parts per Million)

Description	LOS ANGELES AQUEDUCT[a]		COLORADO RIVER	
	Raw water	Treated water	Raw water	Treated water
Calcium	28	21	125	24
Magnesium	10	8	26	6
Total hardness	111	85	420	85
Sodium	43	33	111	37
% sodium	46	46	36	48
Alkalinity	128	80	136	15
Sulfate	45	45	380	87
Chloride	21	21	92	37
Total solids	252	180	845	200

[a] Cation exchanger only.

Case 2. Colorado River.—Many are the possible combinations of various methods of treatment to bring the Colorado River water within the standards stated. Particular attention must be given to the increasing sodium content as hardness is removed, to reduce sulfates, and to be certain that the final water is not corrosive. Without regard to the cost involved, one logical procedure would be as follows:

1. Treatment of the raw water with excess lime to 20 ppm residual alkalinity;
2. Passing 77% of the water through a cation exchanger to a sodium content of 10 ppm and aerating to remove the increased carbon dioxide acidity;
3. Treating the cation effluent in an anion exchanger to zero sulfates and 20 ppm chlorides;
4. Mixing 23% of the excess lime-softened water with the 77% flow which passed the anion exchanger to give a hardness of 70 ppm; and
5. Addition of 15 ppm of calcium carbonate.

The raw water and treated water analyses would be as shown in Table 3, in which the water has been softened to 85 ppm, with a sodium ratio of less than 50%. In this case the sulfates have been lowered to less than 250 ppm, but that was incidental to meeting the other requirements. The chemicals necessary for such a treatment for a million gallons include 915 lb of lime, 5,500 lb of sulfuric acid, 4,700 lb of sodium hydroxide, and 125 lb of calcium carbonate, which would be in the range of \$75 to \$150 per million gal depending upon maximum freight and smallness of plant capacity.

Were the Colorado River water not to be softened to 85 ppm, but to 150 ppm or thereabouts, the problem would be considerably simplified.

Case 3. Treatment of Irrigation Water.—There are many instances in which high sodium and sodium chloride waters may be corrected to the material advantage of irrigation. For instance, a sodium water of 120 ppm with a 50% sodium ratio and a chloride content which should be reduced by 200 ppm could be treated for $15 per acre-ft. It is realized that this cost is relatively high and would be restricted to the more valuable crops; yet waters of this type determine the entire success or complete failure of important irrigation projects.

The writer is not aware of any location where water is treated to remove minerals where irrigation supplies are involved, although there are a number of instances where good and bad waters are mixed so that the mineral content of the water applied to the land shall not be detrimental for agricultural purposes. In the Southwest it has been generally conceded (8) that the sodium ratio (namely, the percentage of sodium in relation to the total calcium, magnesium, and sodium content expressed in equivalent weights) should not exceed 50% except on well-drained soils where a limit of 60 might be tolerated. Values of 70% or 80% are known to be detrimental for agricultural purposes. The presence of a high ratio of calcium and magnesium salts to sodium salts is apparently beneficial on water used for irrigation purposes. It is also known that when relatively hard waters are treated with sodium zeolites such waters used for irrigation purposes destroy lawns and shrubs. This was observed frequently by the writer at Beverly Hills, Calif., where private zeolite plants have been installed at different residences. There are many irrigation supplies in which either the sodium, chloride, or sulfate content is so high that the water cannot be used beneficially for agricultural purposes. Minor corrections in mineral constituents would go a long way toward making successes or failures of many questionable water supplies. Therefore, in the reduction of mineral contents in irrigation waters, there are many cases in which it would be desirable to reduce the sodium ratio.

Case 4. Boiler-Feed Water.—In the treatment of boiler-feed water, it has been necessary to remove solids to control scale formation and corrosion embrittlement, and to reduce carry-over to a minimum. For quite some time, the high carbonate waters have been treated with acid followed by degasifying so that sodium bicarbonate cannot later break down into carbon dioxide and sodium hydroxide in the boiler. It has been found that the increased cost of making water softening equipment acid resistant, together with the cost of acid, is more than offset in many installations by the reduction in total solids and with the resulting decrease in blowdowns (9).

Each boiler-feed problem depends upon the analyses of the water to determine the best type of treatment. Most cases require a reduction in total solids. The total solids of Los Angeles water can be reduced from 225 to 141 by 50% treatment with sodium zeolites and 50% treatment with hydrogen zeolites. High bicarbonates in the sodium zeolite effluent are used to neutralize the acidity produced by the hydrogen zeolite, and the carbon dioxide is removed by aeration. Obviously, water of any total solid content can be produced using mixtures of raw water with treated portions from cation and anion exchangers.

The cost of reducing the highly bicarbonated Los Angeles water by the sodium zeolite and hydrogen zeolite on a fifty-fifty basis is $15 per million gal and for 50% removal as contrasted with only $20 per million gal for complete removal up to 3 or 4 ppm by use of cation and anion exchanges.

Silica is not removed by positive and negative exchangers and heavy coagulation doses of 300 to 400 ppm of alum may be used prior to the zeolite treatment.

Case 5. Special Cases.—Ice plants desire water with total solids of less than 350 ppm. Beer is best when made with a "plastered" water low in sodium salts. Cartridge cases and washed surfaces, requiring clean and bright faces to prevent jamming, need practically distilled water. Color photography requires water with bicarbonates removed.

Cities with concrete sewers and with sulfates present in the water supply would stop disintegration entirely by removing sulfates. Railroad engine water supplies in the Southwest could be treated better by hydrogen and hydroxyl zeolites. Nuisances and efficiency losses at cooling towers where hydrogen sulfide is produced from mineral sulfates could be controlled by the removal of sulfates.

These and other cases indicate many applications in which solids in water may be reduced to an advantage.

CONCLUSION

The development of improved organic zeolites for the removal of positive and negative ions, completely or in part, provides superior methods for softening water, reducing sodium content, removing excess alkalinity, lowering sulfates, or reducing chlorides to produce suitable water for domestic, irrigation, and industrial uses, and in special cases where inconvenience, expense, or failure to secure an adequate working plan are involved. Although the costs of operation in the more aggravated cases may be relatively high, they are in most cases not prohibitive and are certain to be lower as increased production and availability of suitable materials develop.

DISCUSSION

James M. Montgomery,[3] **M. Am. Soc. C. E.**—The results that are being obtained in water treatment make water-works chemists and engineers wonder what the plant of the future will be like. Mr. Goudey has presented an excellent review of the work that is being done in connection with the softening and demineralizing of water by means of base-exchange materials.

The discovery that certain synthetic resins have base-exchange properties is particularly promising for the future because of the infinite number of possible variations in the molecular structure of organic compounds, some of which will probably result in the production of improved materials. The basic principle having been established, organic research chemists no doubt will work to produce materials with greater exchange capacity, improved exchange efficiency, regeneration with less expensive materials, and the property of selective ion removal.

Water softening by base exchange, using either natural or synthetic siliceous zeolites, has been practiced for many years. As a result of this long, and in many cases sad, experience, the properties, both good and bad, of these materials are now well known and, where conditions are right, the materials are used with confidence.

On the other hand, the organic exchange materials are still in the development stage. It is true that carbonaceous zeolites have been used for several years and appear to give good results when used on either the sodium or hydrogen cycle, but the number of installations is too small and the time of service too short for the establishment of definite standards. It is known that the products of some manufacturers have shown a tendency to break down in service and produce black water. Synthetic resins are really in the development stage, and there are but few actual installations, some of which have been disappointing to both customer and manufacturer. Probably a long period of experience, experiment, and education for both manufacturer and user lies ahead before all of the difficulties incident to the use of organic zeolites have been discovered and corrected. Such materials must have a useful life of several years, and unfortunately no satisfactory accelerated tests have ever been developed.

The properties possessed by organic zeolites are remarkable enough without some of the extravagant stories that have been told about them. Contrary to information furnished by certain popular science editors, it is impractical to use them to demineralize sea water. In fact, even if the materials were thoroughly proved by experience, the cost of demineralizing Colorado River water, as shown by Mr. Goudey, is too high to warrant consideration. High exchange capacity is claimed, but it has apparently been accomplished by sacrificing economy.

---

[3] (J. M. Montgomery & Co.), Los Angeles, Calif.

Messrs. Myers, Eastes, and Myers (1) have made determinations of the exchange values achieved by using quantities of salt ranging from 3.11 lb to 81.06 lb per cu ft of zeolite. The use of 3.11 lb per cu ft gave an exchange value of 8,400 grains per cu ft, and 81.06 lb per cu ft gave 29,800 grains per cu ft, with proportionate results for intermediate quantities. The exchange value of 8,400 grains was accomplished by using approximately twice the theoretical quantity of salt. This approaches the economy of good, synthetic, gel-type zeolites. The exchange value of 29,800 grains per cu ft required the use of approximately sixteen times the theoretical quantity of salt. In other words, it would cost eight times as much to operate at 29,800-grains-per-cu-ft exchange value as it would to operate at 8,400 grains per cu ft. Actually, the organic zeolites so far developed would seem to be approximately equivalent to a synthetic gel-type zeolite in both exchange capacity and regenerant consumption when operated in either the sodium, hydrogen, or anion removal cycles at economical exchange values.

When organic zeolites are used in the two-step process for removal of both anions and cations from a water such as the Colorado River supply, which contains a large amount of dissolved solids, the quantity of rinse water required to wash the excess of regenerating materials from the zeolite beds becomes a large item. Sulfuric acid, which is ordinarily used for regenerating the cation removal material, is considerably more difficult to rinse out of a zeolite bed than is salt, and both sodium carbonate and sodium hydroxide, which are usually used for regenerating the anion removal material, are even more difficult to rinse out than sulfuric acid. When the water softening plant of The Metropolitan Water District of Southern California was being designed, investigations were made of the two-step demineralizing process. Statistics furnished by the zeolite manufacturer at that time indicated that the quantity of rinse water that would have to be wasted would amount to 12½% of the total plant influent when treating average water and would increase to about 20% when treating the much harder water that is now stored in Lake Mead (Arizona-Nevada), Lake Havasu (Arizona-California), and Lake Mathews (California), as compared with 2% to 4% at the Colorado River Aqueduct softening plant.

If water could be demineralized economically, this would be an ideal process for reducing both the hardness and the total mineral content of Colorado River water. Some people fear that the high sodium percentage of the softened water will reduce its value for agricultural and horticultural purposes, although twelve years' use of softened municipal water at Beverly Hills, Calif., with a high sodium percentage, has not decreased the beauty of that city's gardens and estates. It seems probable, however, that the plan suggested by Oscar C. Magistad (8) for overcoming the effect, if any, of high sodium water would be satisfactory and practical.

In the Los Angeles (Calif.) area, more people seem to take pride in their lawns and gardens than in any other place in the United States. The beautiful landscaping seen on all sides is not produced as a result of planting and watering alone. Well-kept lawns are torn up, fertilized, and reseeded every few years, and flowers and shrubs require fertilizing frequently. If high sodium water should finally prove, after long use, to be unsatisfactory for domestic irrigation due to the removal of calcium from the soil by base exchange, it would seem that the application of calcium sulfate or possibly ground limestone along with the fertilizer would be both practical and economical. The cost would be small and probably would soon be accepted as a necessary expense incident to the maintenance of good lawns and gardens. The addition of a quantity sufficient to restore the proper calcium-sodium ratio should cost only a dollar or two per year for the average home.

Work such as Mr. Goudey is doing in investigating new base-exchange materials will help to speed the development of improved products. It is to be hoped that he will continue his researches and help to keep water-works chemists and engineers informed of future progress. The Metropolitan Water District, operating the largest zeolite softening plant in the world, also will continue its research, begun at Boulder City, Nev., in 1938. Facilities for such work at the new plant are excellent, and it is hoped that a great amount of constructive work will be done.

George L. Davenport, Jr.,[4] M. Am. Soc. C. E.—The writer's experience of ten years with the use of inorganic zeolite for treatment of water used in locomotives may be summed up as follows:

(1) It is very satisfactory for most waters of 15 grains per gal of hardness or less. The Atchison, Topeka and Sante Fe Railway Company does not usually treat water having less than 5 grains of hardness.

(2) When the hardness is much in excess of 15 grains, the zeolite process will produce treated water that will cause foaming and priming in locomotives, so the railroad must use a lime-soda treatment that will reduce the total solids.

(3) About 50% of the water treated with zeolite causes disintegration of the mineral in excess of the usual annual loss guarantee. Some softening plants run as high as 14% loss of mineral per year. Even then the replacement cost is relatively small, and is insignificant as compared with the advantages gained.

(4) Corrosion of pipe lines and other steel surfaces coming in contact with the softened water can be avoided by using about 50% more wash water than is usually recommended by the manufacturer. It is the practice of the "Sante Fe" to determine the proper quantity of wash water by a silver nitrate test which guarantees that the plant will not be back in service until the salt content in the effluent is within 5 grains of the original salt content of the raw water. This is a very important point which, as a rule, zeolite plant manufacturers do not recognize, since they do not like to admit that so much water should be wasted.

---

[4] Asst. Engr., A. T. & S. F. Ry., Los Angeles, Calif.

(5) Although the "Sante Fe" has obtained estimates on organic zeolite plants, no convincing reason for their use in treatment of locomotive supplies has been presented by the manufacturers. In addition to their higher first cost, there is also to be considered the practical difficulty, in the case of hydrogen cycle plants, of handling acids as compared with salt solutions. Highly trained employees, such as are essential to a large municipal plant, are not available for operating railroad softeners. In fact, the tendency is to eliminate the human element by installing fully automatic zeolite plants, operated by electric motors, which only require occasional services of a man to keep the salt storage tank full.

(6) To summarize, the railroad softening plant is a valuable supplement to the lime-soda process, but cannot take its place for the treatment of most waters in the Western States. Some waters will cause much more loss of zeolite than manufacturers will admit is possible, but even in such cases the operating cost is reasonable and advantages far exceed disadvantages. Long life for piping and equipment using zeolite treated water can be predicted, if sufficient water is wasted in washing out the mineral during the regeneration process.

Use of inorganic zeolite does not appear practicable at the present for railroad water softening due to the high cost of apparatus and lack of skilled attendants. By spending extra money for fully automatic equipment, the ordinary zeolite plant can be made "foolproof" and will render outstanding service, if restricted to treatment of suitable waters.

ROBERT SPURR WESTON,[5] M. AM. SOC. C. E.—The excellent paper by Mr. Goudey shows how much the art of water softening has developed since Thomas Clark of Scotland, about a century ago, patented the process of softening by adding lime water, and J. H. Porter, more than fifty years ago, introduced its sequel, the lime-soda process, at Southampton, England.

Both of these processes have been modified and improved by better arrangements and devices for the coagulation of precipitates and by the use of carbon dioxide and chemical dispersers to prevent the accumulation of carbonates on filter sands and in distribution systems; but even the best of these modified processes has its limits, and reductions of hardness below 80 ppm have been impracticable and difficult in most cases.

The writer first heard of base exchange softening at a conference in Breslau, Germany, when the work of Werner Gans[6] was mentioned in connection with that city's deferrization problem. Since then, the development of zeolite softening has been extensive, and would be wider if communities would only realize, as has the Los Angeles district, that large savings in soap and washed fabrics, and less depreciation of water-using devices, will follow the use of softer water.

[6] "Verbesserung von Trinkwasser u. Gebrauchswasser für hausliche u. gewerbliche Zwecke durch Alluminat-Silicate oder künstliche Zeolithe," by Werner Gans, *Mitteilungen aus der Königlichen Prüfungsanstalt für Wasserversorgung u. Abwasserreinigung*, Berlin, 1907, Heft 8.

Since his first experience with softening by natural zeolite at McKees Rocks, Pa., in 1924,[7] and his later experience at South Orange, N. J.,[8] and elsewhere, the writer has had almost no municipal cases where the residual compounds were in high enough concentrations to be intolerable. He has realized how great the need is for some method of lessening these concentrations however, notably compounds of sodium in many waters which have initial hardnesses of 500 ppm or more.

Following zeolite treatment came the combination treatment with lime and zeolite which enabled one to reduce, to almost any desired degree, the hardness of waters high in sulfates.

Then, early in 1938, there appeared on the market anion and cation exchangers by the use of which, either separately or in combination, not only the hardness but the sodium content could be reduced to zero and the total solids greatly reduced as well. An excellent classification of these zeolites appeared in the author's former paper (7).

It seems almost fanciful that there are durable, organic cation exchanging zeolites on the market which will remove hardening carbonates and bicarbonates in the form of carbon dioxide gas and which may be regenerated with sulfuric acid, which, when combined with calcium, is a superlative water hardener; or, that there are anion exchangers which will remove not only bicarbonates but sulfates, chlorides, and fluorides, with increased acidity of effluent, and which require sodium hydroxide for regeneration.

Therefore, particularly valuable is the description of the author's research work and the clear exposition of the reactions involved. Interesting indeed is the showing that hydrogen zeolites may be used to remove either calcium or magnesium, or both, and that both the hydrogen and sodium cycles may be used on portions of the same water and the two mixed afterward.

All of the great possibilities that have been made available through the improvements in the durability, economy, and efficiency of the organic zeolites should make it possible to say farewell to turbid artificial ice and to boiler scale, to wash windows with waters of the desert, and to wash wool with waters from deep wells.

One rather shrinks from handling sulfuric acid or caustic soda as a regenerator because of the extreme aggressiveness of each in comparison with brine. However, resistant apparatus is available and may be used for successful handling where efficiency and cost are at stake.

One also asks if some of the regenerating chemicals may not be saved and reused, as is part of the brine at South Orange (3), with consequent material saving in cost.

In closing, the writer pleads for a simpler expression of the salt consumption for regenerating zeolites than is involved in the use of the term "grains"; for example, the expression "1.2 lb of hardness per cubic foot" seems simpler than "8,400 grains per cubic foot"—especially to those who think of hardness in terms of parts per million or pounds per million gallons. Likewise, for salt consumption it would be simpler to state "3.0 lb, or parts, of salt per pound, or part, of hardness" than "0.42 lb per 1,000 grains." It is realized, however, that those who treat boiler waters have thought in "grains" for more than half a century.

Harvey F. Ludwig[9] **and Russell G. Ludwig,**[10] **Juniors, Am. Soc. C. E.**—An interesting review of what may be accomplished in the water conditioning field, through the use of various modern zeolites, is contained in this paper. Mr. Goudey does not elaborate upon the basic mechanism by which these zeolites perform their work—namely, that of "ion or adsorption exchange"—and the writers believe that a brief but critical analysis of this exchange phenomenon would be of considerable interest. This basic mechanism has wide and important, but generally unrecognized, application in many engineering fields, particularly in sanitary engineering.

Colloid chemists have determined that the ion exchange properties of zeolitic material in aqueous suspension result from the existence of an electrical double layer surrounding the nucleus or core of each particle. At the surface of the core reside relatively fixed charges or ions ("stabilizing ions") of either positive or negative charge; these make up the inner part of the double layer. The outer section comprises an envelope of oscillating ions ("adsorbed ions" or "exchangeable ions" or "replaceable ions") of opposite charge which diffuses into the surrounding dispersion medium (water). In the ordinary hardness-removing zeolite, for example, each particle (nucleus) is negatively charged, and this is balanced by an outer layer consisting largely, in freshly regenerated zeolites, of sodium ions (Na^+). These adsorbed Na^+ ions are highly dissociated—that is, they oscillate relatively far into the dispersion medium because they are weakly adsorbed.

The degree to which a particular ion will be held or adsorbed by the inner layer may be termed its "exchange adsorbability." The magnitude of this varies inversely with the hydrodynamic size of the ion, and directly with its valence. Ions in aqueous solution are thought to be hydrated or surrounded by a water shell of diameter inversely proportional to the actual size of the ion as it occurs in the crystal lattice. The combined effect of valence and of hydrodynamic size has been expressed[11] by the term "oscillation volume," representing the effective volume occupied by the oscillating ion, or, in other words, the width of the double layer. The smaller the oscillation volume, the more strongly an adsorbed ion is held and the greater its exchange adsorbability. Thus, the cations commonly found in natural waters may be classified in increasing order of their exchange adsorbability as follows: Na^+, K^+, Mg^{++}, Ca^{++}, H^+, Fe^{+++} and Al^{+++}. The trivalent Al^{+++} and Fe^{+++}, when they exist as such, are strongly adsorbed. The action of the H^+ ion is anomalous, but usually it behaves like a weak trivalent cation. The anions may be similarly classified, but in general much less is known of their behavior than of the cations.

[10] San. Eng. Aide, San Pedro, Calif.

[11] "Properties of Colloids," by Hans Jenny, Stanford Univ. Press, Stanford University, Calif., 1938.

If in the dispersion medium there are ions other than those of the diffused outer layer, then the phenomenon of "adsorption exchange" will occur, in which ions initially present in the outer layer are displaced by those from the dispersion medium. The degree to which one ion will displace another will depend upon the relative exchange adsorbabilities and upon the relative concentrations, in accordance with the general mass law. Thus, in the softening of water with ordinary zeolites, the hardness cations, Ca^{++} and Mg^{++}, displace the less strongly adsorbed Na^+ that is initially present in the zeolite and are thereby removed from solution. In the process of regeneration, the weakly adsorbed Na^+ is made to displace Ca^{++} and Mg^{++} by leaching the zeolite with a great preponderance of Na^+. Occasionally some Al^{+++} or Fe^{+++} or H^+ are also adsorbed in the softening operations. These are so strongly held that they may not be appreciably displaced by regeneration, and in time the zeolite "wears out." As noted by Mr. Goudey, wearing out may also occur through disintegration of the zeolite structure in the presence of excessive H^+ or OH^-.

Flocculation of Turbid Waters.—The mechanism of adsorption exchange has a multitude of other applications of interest to the civil engineer. In the flocculation of turbid waters, for example, the phenomenon is particularly important, in that the stability of suspended turbidity (clay) particles results largely from their zeolitic properties. Each particle is surrounded by an electric double layer, the outer section of which consists of various cations (combinations of Na^+, K^+, Ca^{++}, Mg^{++}, and H^+) of positive charge. The particles therefore repel each other, resisting their natural tendency to aggregate; and the forces of repulsion are proportional to the effective width of the double layer. When alum (or a similar coagulant) is added to the system, a portion of this dissociates to form Al^{+++} ions. These replace the cations initially adsorbed and thus reduce the effective width of the double layer to a critical value at which the particles no longer repel each other but instead tend to agglomerate. Another portion of the added alum is converted by hydrolysis (chemical combination with water) to particles or micelles of hydrous aluminum oxide. These are excellent binder material, and when the system is properly mixed or agitated they serve to entrap or "wrap up" the suspended turbidity particles and thereby form large-sized, dense flocs, which will settle out quickly on subsequent standing. The ion exchange reactions are important in this process because by this mechanism the initially stable turbidity particles are rendered unstable, so that they may be entrapped easily by the agglomerating hydrous oxide floc. The "coagulant demand" or dosage of coagulant necessary to flocculate a given water therefore may be considered as comprising two parts—a "perikinetic demand" or that part of the alum which dissociates to form Al^{+++}, and a "binder demand" or that alum which hydrolyzes to give hydrous oxide. (The term "perikinetic" refers to the forces of attraction and repulsion associated with the suspended turbidity particles. The action of Al^{+++} on the system reduces the forces of repulsion such that the particles will tend to aggregate. The system is now "perikinetically flocculated.") The "optimum pH" for any turbid water will be that at which the added alum will dissociate and hydrolyze just as required by the relative magnitudes of the perikinetic and binder demands. These concepts of the mechanics of flocculation were originally presented by the writers in a previous publication.[12] Their studies are being continued in the Sanitary Engineering Laboratories of the University of California, at Berkeley, under the direction of Prof. W. F. Langelier.

Soil Corrosion.—Another important application of the ion exchange principle is found in the study of soil corrosion of pipes. The basic mechanism involved has been termed "contact exchange," and may be demonstrated by hanging an iron nail in a suspension of clay particles containing replaceable H^+ ions. In time it is found that the nail may disappear entirely, and that the clay colloids have acquired a brownish coloration. Evidently the H^+ ions of the clay have been displaced by iron from the nail. This phenomenon is undoubtedly important in the corrosion of metallic pipes laid in soils containing replaceable hydrogen. Similarly, the deterioration of concrete pipe laid in soils containing adsorbed Mg^{++} properly may be attributed to replacement of Ca^{++} by Mg^{++}.

The question arises here as to just what adsorbed cations might be expected to occur in the soils of a given geographical region. Both the total concentration of adsorbed cations (called the "saturation capacity" or "base exchange") and the specific types present will depend largely upon climate, particularly upon annual rainfall.[13] The adsorbed cations in soils are associated with those soil particles of colloidal size (about 1 μ and less), termed the soil colloids; these include both the inorganic colloids (clay) and the organic humus colloids. The adsorbed cations generally include Na^+, K^+, Ca^{++}, Mg^{++}, and H^+; and the saturation capacity is usually expressed as the sum of the exchangeable bases (Na^+, K^+, Ca^{++}, Mg^{++}) plus the exchangeable hydrogen (H^+), all measured in milligram equivalents per 100 grams of soil. In arid regions the soils (alkali soils) contain relatively few colloids and therefore have low saturation capacities; the replaceable cations are all exchangeable bases (about 50% Na^+ and K^+, and about 50% Ca^{++} and Mg^{++}), there being no exchangeable hydrogen. When the annual rainfall becomes appreciable (in the magnitude of 25 in.), the leaching action of the percolating water results in replacement of some of the exchangeable bases by H^+ ions derived from the free carbonic acid in the water that percolates through the soil. Simultaneously, there is an increase in the saturation capacity, because the increased percolation hastens the weathering processes by which the noncolloidal primary soil minerals are converted into colloidal particles (clay), and because the increase in vegetation associated with increased rainfall increases the concentration of the humus colloids. In such soils (chernozems) the adsorbed cations comprise from 1% to 10% each of Na^+, K^+, Mg^{++}, and H^+, with about 75% Ca^{++}. Finally, in the very humid regions, the soils (podsols) are of very high saturation capacity and comprise about 70% H^+ with the remainder mostly Ca^{++} and Mg^{++}, there being little or no Na^+ or K^+.

[12] "Laboratory Flocculation of East Bay Sewage, and the Mechanism of Flocculation in Water Purification and Sewage Treatment Practice," by H. F. Ludwig and R. G. Ludwig, *California Sewage Works Journal*, Vol. 13 (1941), pp. 54–80.

[13] "Factors of Soil Formation," by Hans Jenny, McGraw-Hill Book Co., Inc., New York, N. Y., 1941.

It is interesting to note that the physical and chemical properties of soils are generally controlled by the magnitude and nature of the soil colloids, although these usually are only a fraction of the total soil mass (about 10% in ordinary loams, for example). Further, the properties of these colloids are largely determined by the concentration and nature of their exchangeable cations, and these represent only about 5% of the soil colloid mass. Thus, the properties of a soil are determined essentially by its exchangeable cation content, which generally comprises less than 1% of the entire soil mass.

These two examples have served to illustrate how prevalent and important ion exchange reactions may be. There are many other instances, as, for example, in the fields of sewage treatment, highway construction, irrigation, etc.

UNUSUAL EVENTS AND THEIR RELATION TO FEDERAL WATER POLICIES

BY W. G. HOYT,[1] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. EDWARD H. SARGENT, DANA M. WOOD, JAMES S. SWEET, J. L. CAMPBELL, DAVID J. GUY, ALBERT S. FRY, AND W. G. HOYT.

SYNOPSIS

Within the 10-yr period between 1930 and 1940 there were profound changes in federal water policies and more than a tenfold increase in federal activities designed to modify the runoff phase of the rainfall-runoff cycle. The total federal expenditures for all purposes increased only about two and one-half fold during the same decade. During the fiscal year 1940 alone, some \$500,000,000 or \$600,000,000 of federal money were spent on measures and practices relating to storage and appurtenant works for irrigation, power, flood control, water supply, water spreading, debris control, recreation, and wild-life refuge; upstream engineering, agricultural, and land-use measures and practices; and all related activities designed to obtain beneficial conservation, control, regulation, and use of water. During 1930 the sum of money so expended was only about one tenth as much. The purpose of this paper is to inquire into the basic reasons underlying the changes in water policies and the large increase in activities and to discuss in a general way their extent, aims, and objectives.

INTRODUCTION

Many may feel that the large increase in water conservation activities is directly in accord with the long-established trend toward centralization of governmental responsibilities and corresponding expansion in federal public works. Others feel that the increase has been mainly due to the crossing of a new and largely unexplored frontier and to a normal, though rapid, expansion in long-deferred conservation and wise utilization of soils and waters, which are unquestionably two of the vital natural resources of the United States. Still others feel that social security, which was certainly a major political consideration, was the principal motivating force. All of these explanations may be safely assumed to be valid in some degree.

NOTE.—Published in February, 1942, *Proceedings*.

[1] Hydr. Engr. (Prin.), Water Resources Branch, U. S. Geological Survey, Washington, D. C.

Although recognizing the futility of attempting to evaluate the relative importance of many contributing causes that are obviously interrelated, it would appear that the indicated increase in activities relating to the conservation and control of water can be ascribed largely to the concurrent effect of the following three types of happenings:

(1) The 1930–1940 decade was characterized by a degree of Nation-wide abnormality with respect to climatic and hydrologic conditions that has probably not been exceeded during the past century;

(2) The impact of an economic crisis with chronic symptoms that began in 1929, and the associated depression, brought about changes in political leadership as well as modifications in governmental theory; and

(3) There is a belated Nation-wide recognition that the wastage of soil and water is a genuine menace to the national welfare.

Obviously these three reasons are closely related. For example, the abnormality with respect to meteorologic and hydrologic conditions created the necessity for the rehabilitation of devastated areas, the repair of damage resulting from the unusual events, and the construction activities looking toward alleviation of future occurrences. These in turn provided an outlet for relief work and funds that were made available as a result of the economic crisis. In addition, the visible evidences of the erosion and loss of fertile soil, and its transportation and deposition associated with the widespread floods and with the conditions arising from deficiencies in water supply during droughts, undoubtedly hastened the adoption of federal policies relating to the conservation of soil and water and to the control of floods.

The unusual meteorologic conditions relate largely to droughts and floods. Since 1889 there have been eleven well-recognized drought years in the United States. It is not fully realized, perhaps, that five of these major droughts of record occurred during the 10 years 1930 to 1940, as follows:

Year	Drought area
1930	Practically all states east of the Mississippi River, California, Oregon, Washington, North Dakota, and Montana
1931	Northern Great Plains, Idaho, Utah, Colorado, and the Southeastern States
1933	Upper Mississippi Valley, Nevada and Utah, South Central Plains, and Southeastern States
1934	Practically all of the United States except the Atlantic seaboard, Southern States, and Southeastern States
1936	All of the Mississippi River Valley and northern Great Plains, and Pacific Northwest

The history of these droughts and their significance in relation to climate are so fully recorded in technical reports[2] that it seems unnecessary to do more than to list them. They had a decided impact on national affairs and were directly responsible for many new national policies.

---

[2] "Droughts of 1930–34," by John C. Hoyt, *Water-Supply Paper No. 680*, U. S. Geological Survey, 1936; also "Drought of 1936," by the same author, *Water-Supply Paper No. 820*, U. S. Geological Survey, 1938.

Floods, like droughts, also affected all parts of the Nation. Stages and discharges, and resulting damage in basin after basin, broke all historic records.

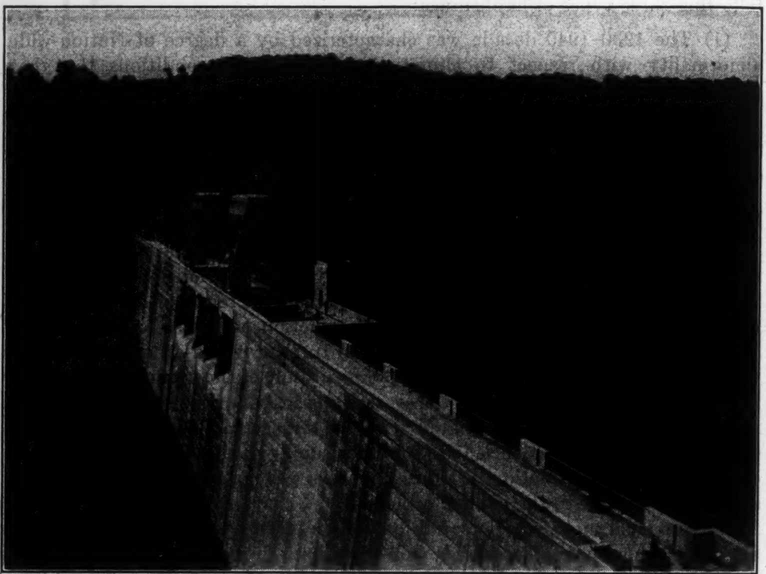

Fig. 1.—Floods, Like Droughts, Also Affected All Parts of the Nation. Mahoning Creek Dam in Western Pennsylvania Is One of Six Dams Designed as a Part of the War Department's Comprehensive Program for the Control of Floods in the Upper Ohio River Basin Above Pittsburgh, Pa.

These flood events occurred generally during the last half of the decade on river basins as follows:

Time	Region
1934:	
January	La Cañada Valley, California
1935:	
May and June	Republican and Kansas rivers in Colorado, Nebraska, and Kansas; and the Nueces and Rio Grande basins in Texas
July	Central New York
August	Muskingum River, Ohio
1936:	
March	All river basins in Northeastern United States from Ohio, West Virginia, and Virginia through to Maine
July and September	Neches, Guadalupe, Concho, and San Saba rivers in Texas

Time	Region
1937:	
January and February	Entire Ohio River Basin
March	Throughout the central upper Mississippi Valley, southern Wisconsin, eastern Iowa, and Illinois
May and June	Canadian and Pecos rivers, New Mexico
December	All of California north of Tehachapi Pass
1938:	
March	All of southern California
September[3]	Hurricane storm wave and flood in New England—believed probably to have destroyed more lives and property than any previous single natural disaster in the history of the United States
1940:	
August	South Atlantic region
November	All of eastern Texas

In addition to the foregoing major flood areas, major and record-breaking floods occurred in scattered areas on smaller streams. Although not absolutely indicative of the unusualness of the past decade with respect to floods, it seems very significant that, out of 6,792 maximum peak discharges covering all available records through September, 1938,[4] 3,137, or nearly 50%, occurred during the 8-yr period ending in 1938. With respect to the March, 1936, flood and the flood of January and February, 1937, in the Ohio River Basin, geologic evidence, suggestive rather than compelling, seems to show that in parts of the area they exceed in height any previous flood. Most of the other floods listed are clearly outstanding and unusual as shown by Myers' scale or other ratings.

It is not surprising to one acquainted with the meteorologic and hydrologic history of, and the resulting damage caused by, these events that the droughts brought home forcefully to the entire Nation the value of water in connection with its economic development or that the cataclysmic flood events made a deeper impression on policy makers, than ever before, of the need for a comprehensive program involving Nation-wide flood control with incidental benefits to power, navigation, irrigation, recreation, and related values.

Although it is somewhat difficult to ascribe definite reasons for the rapid transition of a wide popular movement or belief into an active action program, it is probably fair to state that the drought in 1930 had much to do with the initiation of land-planning and water-planning activities as a distinct federal function; that the recurring droughts during the period 1930 to 1936 resulted in an enlargement of the federal reclamation idea from one of large developments on arid lands to an all-embracing use of water for irrigation of both large and small areas in which problems of population shifts and resettlement played an important part for the first time since the elimination of the Nation's geographic frontier; that the widespread disastrous floods resulted in extension of federal flood-control activities from navigable and interstate streams to include others that affect the general welfare, regardless of the size of channel in which they occur, and, what is perhaps more significant, to include so-called "upstream engineering" as an integral part of the flood-control operations; and that the combined occurrences of both unusual floods and droughts resulted in new and extensive federal measures relating to the conservation of soil and water. No one can state definitely whether or not the unusual climatic manifestations would have resulted in new policies and related activities had they not occurred during a period when national affairs were being modified in an effort to overcome an economic depression. The droughts and floods were so unusual that, coming at any time, they would have created an urge, which no doubt would have been translated into definite action programs, at least to some extent, even under more normal economic and political conditions. The only question relates probably to the magnitude of the action program. It is sufficient for the present discussion to indicate that during 1940 hydraulic engineers in federal services were engaged on a far greater number of projects and on a far greater scale than in 1930, and that federal interests in water have grown to enormous proportions during the past decade. This interest has found expression in several different, though related, channels.

NATIONAL WATER PLANNING

Prior to 1930 there was no single federal agency that devoted itself exclusively to water planning from a national standpoint. Agencies such as the Corps of Engineers, Bureau of Reclamation, and the Geological Survey had collected, compiled, and published a vast amount of basic technical information concerning the Nation's developed and undeveloped potentialities and possibilities. Moreover, just prior to the decade in question, the major floods during the spring of 1927 in the Mississippi Valley and the comprehensive report on the Tennessee River and tributaries by the Corps of Engineers were responsible, in part, for the legislation that resulted in the "308" reports by the Corps of Engineers in which was outlined technical information concerning water problems in all major basins in the United States. In these various agencies, therefore, there was a vast reservoir of technical information that made possible the early initiation of many of the major flood-control and multiple-use projects hereinafter listed.

Early in 1934 the urgent need of large federal public works projects for the unemployment relief program led Congress, on February 2, 1934, to ask the President for a comprehensive plan for the improvement and development of the rivers of the United States that would give information for the guidance of legislation to provide maximum multiple-purpose benefits. Accordingly, the President appointed promptly the secretaries of the Interior, War, Agriculture, and Labor departments to advise on the development of a water policy and on the choice of projects; and on February 20, 1934, they appointed six technical subcomitttees, each assigned to a selected geographical region. The Cabinet

Committee (referred to as "The President's Committee on Water Flow") on April 20, 1934, rendered its report to the President with qualifying or supplemental individual statements by the secretaries of War, Agriculture, and Labor. Although this composite report was made in great haste for the primary purpose of determining, quickly, construction projects of highest over-all merit in the unemployment-relief program, it is important in the record of interagency coordination in water planning.

Returning now to consideration of natural phenomena as a major influence, the droughts of the early 1930's seemed to emphasize that in addition to engineering problems it was necessary also to consider their relation to the over-all economic, social, and land problems which had then assumed such great proportions. This situation led to the appointment in 1933 of the Mississippi Valley Committee of the Emergency Administration of Public Works (PWA) which, through a series of administrative changes, became the Water Resources Committee of the National Resources Planning Board. Under the Reorganization Act of 1939 and the Presidential Reorganization Plan No. 4 (April 11, 1940), this Board became a part of the Executive Office of the President, reporting directly to him. It is perhaps significant that the first line in the first planning report—namely, "Report of the Mississippi Valley Committee" dated October 1, 1934—is a quotation credited to Charles D. Norton: "Make no little plans. They have no magic to stir men's souls."[5] No one can gainsay but that this admonition set a keynote and has been adhered to by subsequent committees. Probably no one federal agency has enlisted the services (largely voluntary) of more hydraulic engineers and hydrologists in its planning operations than has the National Resources Planning Board; and many of these men are engaged today on its forty-five drainage basin committees created to facilitate cooperation among federal and state agencies in the conduct of investigations of water in relation to navigation, power, municipal water supply, erosion, irrigation, forestry, floods, droughts, and wildlife conservation. The basin reports of the Water Resources Committee, in which are outlined water problems and programs, contain a wealth of information which has not only been of value in connection with present public works projects but which will increase in value as time goes on. Those interested in hydrology, as such, will no doubt find much of interest in two reports prepared under the auspices of the Water Resources Committee—namely, "Deficiencies in Hydrologic Data" and "Deficiencies in Hydrologic Research."

FLOOD CONTROL

As has already been indicated, federal (as distinct from non-federal agencies, which had been active in flood-control operations and which include, among others, the Miami Conservancy District, as an aftermath of the 1921 flood, and the Los Angeles Flood Control District) flood activities prior to 1930 were generally incidental to navigation and were conducted largely as a function of the Corps of Engineers. These activities were directed principally toward the control of flood waters by levees and improvement of the channels of navigable or interstate rivers. The cataclysmic flood events of the past decade, however, greatly modified and enlarged the federal policy and federal participation in relation to flood control in two notable respects: First, by the adoption of a policy which extended the scope of control of floods that affect human life and property, whatever the size of the rivers and channels; and second, by Congressional recognition[6] of a relation between land use and floods and the necessity for a coordinated land-use and water-regulation program for flood control. These two modifications or enlargements of policy not only increased the activities of the Corps of Engineers but also brought the Department of Agriculture "into the picture" as an active flood-control agency. Here again the increased and new activities demanded the effective service of hydraulic engineers. For example, under the Flood Control Act of 1936, Congress authorized some 270 flood-control projects (most of which had been investigated and reported on in the "308" reports), including many dams and reservoirs with an estimated construction cost in excess of $300,000,000 located in thirty-one states and affecting nearly every state in the Union.

---

[5] Report of the Mississippi Valley Committee of the Public Works Administration, October 1, 1934, p. 3.

The Flood Control Act approved on June 28, 1938, authorized additional flood-control improvements in nineteen separate river basins, or parts of basins, and authorized the sum of $370,000,000 for the construction of the projects included in this Act. In addition to actual construction projects, these acts also authorized the Departments of War and Agriculture to make preliminary examinations and surveys for flood control at some 345 locations. One important feature of the enlarged policy was the expressed obligation for the federal government to assume a larger share of the cost of flood-control operations, which had heretofore been a local responsibility. An outstanding example relates to the reimbursement (Act of June 28, 1938) of the Muskingum Conservancy District for expenditures made by the District in acquiring lands and right of ways for the series of fourteen reservoirs in the Muskingum River Drainage Basin and the inclusion (Act of August 11, 1939) of the reservoirs in the flood-control plan for the Ohio River.

Congressional recognition of a relation between land use and floods and the necessity for a coordinated land-use program for flood control naturally greatly increased flood-control activities in the Department of Agriculture, which since 1938 has been conducting flood-control surveys and developing programs for the reduction of flood damages by the treatment of lands on which floods originate. Preliminary examinations have been completed on more than two hundred watersheds aggregating in area more than 1,000,000 sq miles. Detailed surveys have been initiated on forty-two watersheds having a total area of 265,000 sq miles. Flood-control survey reports had been completed for sixteen of these basins by the end of 1941. Treatment of one of the surveyed watersheds has been initiated. In the Department of Agriculture, especially, the hydrologists have had to play a very important part since it was necessary to evaluate not only the relation between precipitation, land use, and flood runoff but also to predict how these relationships would be modified by changes in land use.

---

[6] Flood Control Act, June 22, 1936.

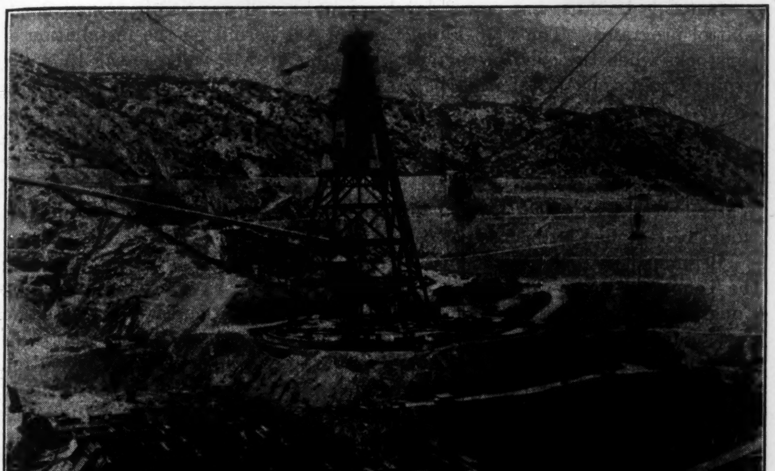

FIG. 2.—NOT ONLY LAND USE BUT POWER DEVELOPMENT WAS TIED IN TO NEW FLOOD-CONTROL PROGRAMS. CRESCENT-SHAPED SHASTA DAM WHICH IS MORE MASSIVE THAN BOULDER AND TALLER THAN GRAND COULEE IS DESIGNED TO MEET THE EVER-INCREASING DEMAND FOR POWER IN THE DEFENSE INDUSTRIES OF NORTHERN CALIFORNIA. THIS DAM, THE PRINCIPAL ENGINEERING FEATURE OF THE CENTRAL VALLEY PROJECT IN CALIFORNIA, WILL ALSO AID IN FLOOD CONTROL, NAVIGATION, IRRIGATION AND THE REPULSION OF SALT WATER FROM THE DELTA FARMING AREA

WATER POWER

Not only land use but power development as well was tied in to new flood-control programs. The 1936 Flood Control Act permitted the installation of penstocks when the chief of engineers recommended it, whereas the 1938 Act required that such installation be made when recommended by the Federal Power Commission. The latter Act made specific appropriations to be expended by the Federal Power Commission in conducting any necessary investigations or surveys. This step toward federal development of the power by-product was apparently an extension of the power policy of the Federal Water Power Act of 1920, under which all power equipment and appurtenances would be installed by licensees.

Beginning with the Boulder Dam Act of 1928, various projects, including the Tennessee Valley Authority (TVA) developments, have been approved by Congress. This indicates a disposition on the part of Congress to favor actual development by the federal government much more than theretofore. This generalization applies whether the primary purpose be navigation, flood control, or reclamation, although the greatest evidence of the changed policy is disclosed through flood-control measures which, in turn, are the outgrowth of the 1930–1940 flood situation already described.

MULTIPLE-USE PROJECTS

Prior to 1930 the operation of most public water projects related chiefly to a single purpose such as the maintenance of navigation or the storage, release, and distribution of water for irrigation. Since 1930 there has been a profound change in federal participation in multiple-use water projects. A few of these projects, however, represented the consummation of plans proposed prior to 1930 and, therefore, may not be directly related to meteorologic and hydrologic events since 1930. Two such major developments are: The Boulder Dam on the Colorado River, constructed under the Act of 1928, based on earlier reports and examinations, and the Central Valley Project of California, which had its inception in reports by the state engineer of California made prior to 1930. Most of the multiple-use projects, however, have had their inception since 1930 and are more or less related to the train of events since that date. These larger projects are (1) TVA; (2) Fort Peck Dam, in Montana; and (3) Columbia Basin Project.

(1) The all-inclusive TVA (Act of May, 1933) was born in the stress of the swiftly moving days of 1933. The initiation of its chain of navigation, flood-control, and power dams was greatly facilitated by the "308" reports of the Corps of Engineers previously mentioned. Its upstream operations embraced water conservation, erosion, forestry, and land use "in the interests of National defense and for agricultural and industrial development and to improve navigation in the Tennessee River and to control destructive flood waters in the Tennessee River and Mississippi River Basin."[7]

(2) The largest earth dam in the world at Fort Peck, on the Missouri River, was designed to store 19,000,000 acre-ft of water, with its primary engineering

---

[7] From preamble, Act of May, 1933.

purpose the improvement of river navigation from Sioux City, Iowa, to the mouth of the Missouri River, a distance of 764 miles, with incidental purposes of flood control, hydroelectric power, and irrigation. In addition to the strictly engineering purposes, the dam was initiated to provide work for unemployment. More than 53,000,000 man-hr had been expended on the project to April 15, 1939. For comparison as to the work relief features, it may be of interest to state that the total man-hours by the Civilian Conservation Corps (CCC) directed by the Soil Conservation Service on forestry, soil erosion, flood control, and similar projects from the beginning of operations through December, 1940, was 67,738,591 man-hr.[8]

(3) The Columbia Basin Project and the Grand Coulee Dam on the upper Columbia River, in the State of Washington (the largest single structure ever to be constructed by man and containing enough material to build a concrete road a distance of 5,600 miles), will be used for irrigation, power, flood control, and navigation.

Other projects include the Bonneville development on the Columbia River near Portland, Ore.; the fourteen dams and reservoirs in the Muskingum River Basin, Ohio; the Conchas Dam on the South Canadian River in New Mexico; the Sardis Dam on the Little Tallahatchie River in Mississippi; the Buchanan and Marshall Ford dams on the Colorado River in Texas; the Tygart River Dam in West Virginia; the Santee-Cooper development in South Carolina; and others.

As an example of the magnitude of these and other new great developments, it may be stated that the storage capacity thus made available exceeds 80,000,000 acre-ft, or considerably more than the combined capacity of all reservoirs that had been constructed for all purposes in the United States prior to 1930. The design, construction, and operation of these structures have naturally resulted in vastly increased staffs of the Bureau of Reclamation and the U. S. Engineer Department, the two agencies most actively engaged on the projects. Problems relating to hydraulic engineering and hydrology have been paramount in their design and operation since it was necessary not only that the project works be safe, but that they should effectively perform their multiple-use purposes for navigation, flood control, power, irrigation, domestic water supply, and the real, though intangible, benefits such as recreation, wildlife conservation, National Defense, economic rehabilitation, and the like.

SOIL AND WATER CONSERVATION

Prior to 1930 soil and water conservation activities as a distinct identity separate and apart from federal irrigation, unquestionably the first major federal soil and water-conservation activity, were directed largely toward experimental research and demonstration projects in the Bureau of Agricultural Engineering, Bureau of Chemistry and Soils, and Forest Service in the Department of Agriculture. In the Interior Department, the Geological Survey, since the days of Maj. J. W. Powell, has been active in studies and measures looking toward wise use of land and water resources. Although the need for conservation of soil and water was fully realized by many, the droughts and floods provided a stimulus whereby the research activities were translated into a vast action program, first (1933) in the Interior Department under PWA and later (1935) in the Department of Agriculture. The Soil Conservation Act of April 27, 1935,[9] states in its preamble "that the wastage of soil and moisture resources on farm, grazing, and forest lands of the Nation, resulting from soil erosion, is a menace to national welfare" and declares the policy of Congress

---

[8] The C.C.C.'s Eighth Birthday," by G. H. Gilbertson, *Soil Conservation*, SCS, April, 1941, p. 262.

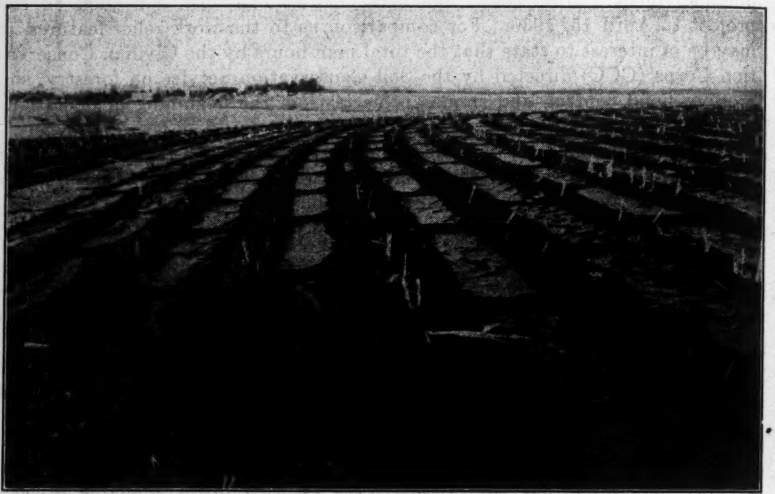

FIG. 3.—THE WASTAGE OF SOIL AND MOISTURE RESOURCES RESULTING FROM SOIL EROSION IS A MENACE TO NATIONAL WELFARE (A BASIN LISTED FIELD ARRANGED TO CONSERVE MOISTURE AND PREVENT MOVEMENT OF WATER ALONG THE FURROWS)

> "to provide permanently for the control and prevention of soil erosion and thereby to preserve natural resources, control floods, prevent impairment of reservoirs, and maintain navigability of rivers and harbors, protect public health, public land and relieve unemployment."

The unusual events also played a large part in the enactment of Soil Conservation District laws in practically every state and the establishment of Soil Conservation districts embracing more than 66,000,000 acres of land, as is evidenced by the fact that the first sentence of a letter by the President, dated February 26, 1937, to the Governors of all states, expressing the hope that state conservation laws would be adopted, reads as follows: "The dust storms and the floods of the last few years have underscored the importance of programs to control soil erosion." Prior to Reorganization Order No. 4, dated April 11, 1940, activities under the Soil Conservation Act were confined to the Department of Agriculture, but under the terms of the Presidential Order No. 4, soil and moisture conservation activities were transferred to the Department of the Interior in so far as about 280,000,000 acres of Indian, grazing, national park, and other lands under its jurisdiction are concerned.

---

[9] 49 Stat. 163, 16 USC 598.

Closely allied with the purpose of the Soil Conservation Act is the so-called Taylor Grazing Act of June, 1934, which provides for the conservation of soil and water on the vast public domain of the West through the creation and administration of grazing districts. Under this act the Department of the Interior regulates grazing and other forms of land use on some 150,000,000 acres of land that theretofore were subject to entry under the public land laws. Also, under the provisions of the National Industrial Recovery Act of June 16, 1933, all public lands in the eastern and central Western States were withdrawn from entry in February, 1935, by executive order in the interests of conservation of natural resources including "control, utilization and purification of waters, prevention of soil and coastal erosion and flood control."

Thus, since 1930 the Nation has witnessed the expansion of soil and moisture conservation activities as such (and apart from irrigation) from research into a Nation-wide action and educational program by two major federal departments. In addition to providing an outlet for the employment of the CCC, Works Progress Administration (WPA), and similar "work relief" organizations, this development has increased many times the number of hydraulic engineers in the government service.

IRRIGATION AND WATER FACILITIES

Prior to 1930 federal activities in connection with irrigation were conducted chiefly by the Department of the Interior under the Act of June 17, 1902, and amendments thereof, commonly known as the Reclamation Act, and under several specific acts relating to the development of irrigation facilities on Indian lands. Under the Reclamation Act, millions of acres of arid lands of the West had been transformed into productive farms, and substantially all expenditures relating thereto had been on a basis of repayment by water users. Not including Indian lands, most of the projects involved public lands, and economic problems relating to resettlement and population shifts were not generally of primary consideration. Although the federal government was vitally interested in the relation between the adequacy of water to the individual water user on the project, it was not especially concerned with the farmer or rancher on private lands outside of federal projects.

The water shortages throughout the Great Plains, the dust storms, and the human suffering associated with the recurring droughts to which attention has been called led to the passage of three acts, all of which have materially increased federal activity with respect to water. These acts authorized the creation of the now well-known AAA, or Agricultural Adjustment Administration, the Farm Security Administration, and the Water Facilities, all in the Department of Agriculture. Under these acts, investigations, loans, general planning, and home-management guidance, relating to the construction and development of ponds, reservoirs, wells, dams, springs, pumping works, windmills, water spreaders, stock-water tanks, flood irrigation, and small irrigation systems for single farms or small groups of farms, are authorized with not more than $50,000 of federal funds to be expended on a single project.

In addition, the Wheeler-Case Act (August 11, 1939) authorized the Secretary of the Interior to construct water-conservation and utilization projects in the Great Plains area and elsewhere. This is apparently a new type of conservation legislation involving cooperation between the Bureau of Reclamation, Office of Indian Affairs, Department of Agriculture, federal relief agencies, and local state or political subdivisions, the water users (except Indians, who are dealt with by specific legislation) repaying, over a period of 40 years, all of the allotments from appropriations made for the purpose and, in addition, any amount from "relief funds" directed by the President.

In all these new activities, hydrology has played an important part, since one of the primary purposes of the activities relates to the development of dependable water supplies in regions where the supplies are not only scanty but where, in general, prior development has used the "cream," as it were, of the water. In contrast to 1930, it is now possible under existing laws for any landowner or operator under certain conditions to avail himself of financial and technical help in the development of dependable water supplies for irrigation, stock, and domestic uses.

HYDROLOGIC RESEARCH AND FACT FINDING

As of 1930, federal hydrologic research was restricted generally to a few experimental areas maintained by the Department of Agriculture under the terms of the McSweeney-McNary Forest Research Act or earlier authorization, at which the intricate relationships between rainfall and runoff were determined. The fact-finding activities related largely to the Weather Bureau in connection with the collection of rainfall, snowfall, and temperature records and to the Geological Survey in connection with the Nation-wide collection of records of stream flow, ground water, and quality of water. As a coordinated part of all of the activities previously described, there has been, since 1930, a pronounced increase in hydrologic research activities as a whole, and a substantial, although not proportional, increase in the activities of the Weather Bureau and the Geological Survey as they relate to the collection of basic meteorologic and hydrologic data. The increase in hydrologic research has taken the form, principally, of:

(*a*) Expanded scope and increase in the number of experimental areas maintained by the Soil Conservation Service and the Forest Service for the purpose of determining the intricate relations between rainfall, runoff, soil moisture, and soil movement under different climatic, physiographic, and geologic conditions, and the effect of cover and land use on such relationships.

(*b*) The investigation by the U. S. Engineer Department of approximately 1,000 major storms in the United States involving the compilation of basic precipitation from all available sources; the preparation of isohyetal maps and, for the more important storms, the construction of mass rainfall curves; and computation of duration depth-area curves by 6-hr intervals.

(*c*) Increased activity of the Geological Survey with respect to the analyses of hydrologic and meteorologic phenomena associated with floods and droughts.

(*d*) Expanded hydrologic studies by the Weather Bureau in connection with its enlarged program of flood forecasting and establishment of a hydrometeorological section in which mass rainfall curves prepared by the U. S. Engineer Department are reviewed in connection with synoptic analyses, and in which special meteorological studies are made to determine limiting precipitation rates in certain drainage basins.

(*e*) Coordinated efforts of the Soil Conservation Service and the Forest Service on hydrologic problems involved in the flood-control activities of the Department of Agriculture.

The increase in availability of basic meteorologic and hydrologic data relates principally to the increase in the number of precipitation stations, more especially the network of recording rain gages installed and maintained by the Weather Bureau in connection with its Nation-wide coverage, made possible in large part by the cooperation of the Corps of Engineers and flood-control agencies in the Department of Agriculture; the dense network in Ohio by the Soil Conservation Service in connection with its microclimatic studies; the increase in snow observations; and the increase in the number of river-measurement stations and ground-water observation wells maintained by the Geological Survey that have been occasioned by the demands of, and made possible by, the cooperation of many federal and non-federal agencies engaged on flood control, irrigation, and related problems. There also may be added numerous fact-finding projects in hydraulic laboratories and experimental areas relating to evaporation, transpiration, wave movement, debris movement, suspended load, and others either independently or jointly by the Corps of Engineers, Geological Survey, Department of Agriculture, Bureau of Reclamation, TVA, and other agencies.

CONCLUSION

In retrospect it has been made to appear, perhaps, that the water policies outlined were adopted and put into practice in a more orderly sequence and manner than was actually the case. In the war against the depression and unusual climatic and hydrologic conditions of the 1930's, however, as in the present defense activities, there was undoubtedly considerable stress and confusion. Parts of the activities were acknowledged to be experimental. It is too much to hope that under such conditions all policies and practices would ever be intrinscially sound. Future experience may be expected to show that some modifications are needed.

Engineers had considerable to do with the design and planning of projects and also with the formation of policies, although there may be considerable disagreement as to the validity of all the policies. Engineers also have had much to do with the prosecution of the newly authorized activities. Out of their combined experiences should come expressions of opinion and ultimately a knowledge that should have weight in the guidance of future changes and trends. To that extent, as well as in the accomplishment of sound results, the new situation presents a definite challenge to the profession.

ACKNOWLEDGMENT

For the photographic views in this paper the writer is indebted to three important agencies of the federal government. Fig. 1 is supplied through the courtesy of the U. S. Engineer Department; Fig. 2 is from the Bureau of Reclamation; and Fig. 3 is from the Soil Conservation Service.

DISCUSSION

Edward H. Sargent,[10] **M. Am. Soc. C. E.**—The author is to be congratulated on his splendid paper describing the basic reasons underlying the changes in the federal water policies in the decade from 1930 to 1940.

The gates of the Conklingville Dam creating the Sacandaga Reservoir, constructed by the Hudson River Regulating District on the Sacandaga River, the principal tributary of the upper Hudson River, were first closed on March 27, 1930, impounding that spring's flood waters. This reservoir has an available capacity of 760,000 acre-ft, and release of the stored water for the regulation of the flow of the Hudson River for the public welfare, including navigation, sanitary improvement, and power, began on July 1, 1930.

With reference to the author's statement (see heading "Multiple-Use Projects") that, "Since 1930 there has been a profound change in federal participation in multiple-use water projects," the writer feels that the success of the Sacandaga Reservoir in achieving these multiple purposes contributed to the changing of the current engineering opinion regarding such functioning.

Dana M. Wood,[11] **M. Am. Soc. C. E.**—This excellent paper rightly stresses the impetus given to multi-purpose planning by quite recent events. However, the trend has existed even from the earliest days of the Nation, and was strong long before the past decade. Also, this paper is based largely upon the effects of Congressional acts, whereas innumerable court decisions also have had a very definite part in broadening federal water policies. Of course, both the Congress and the courts consist of men influenced by the social impacts of droughts and floods, as well as economic and war stresses. All these factors have been present from earliest days.

At least two other papers should be read along with this one to clarify the broad background for present federal water policies. In 1938, James L. Fly[12] presented the legal development of federal policies with respect to navigation, flood control, irrigation, and finally planning for multi-purposes. Further progress has been made since that date. David E. Lilienthal and Robert H. Marquis, in 1941,[13] emphasized the expansion of governmental business activities and the advantages of the government corporation for the administration and development of multi-purpose projects. Both papers definitely indicate why recent rapid advances in policies and accomplishments have been possible.

One reason why so much progress could be made during the past decade may lie in the tremendous advance made in the arts during the previous two decades. Engineers were prepared to accomplish great things when the need became urgent.

[11] Head Hydr. Engr., TVA, Knoxville, Tenn.

[12] "The Rôle of the Federal Government in the Conservation and Utilization of Water Resources," by James Lawrence Fly, *Pennsylvania Law Review*, Vol. 86, No. 3, January, 1938.

[13] "The Conduct of Business Enterprises by the Federal Government," by David E. Lilienthal and Robert H. Marquis, *Harvard Law Review*, Vol. 54, No. 4 ,February, 1941.

The writer had occasion recently to ask the U. S. Weather Bureau for its definition of a drought, and was much surprised to learn that the best it had to offer, in a hurry, was "any time when there is insufficient moisture to support the continued growth of vegetation." The author lists several years during which critically low runoffs occurred in different areas. In the comprehensive development of any single, large watershed, it will be found that consideration must be given to critically low periods lasting two years, three years, or even longer. This is important with respect to hold-over storage problems from one year to another during such periods. Considering the high degree of regulation possible after 1945 in the Tennessee Valley, indications (in advance of complete runoff records) are that the most severe drought of record has lasted from 1939 into the current year (1942), with the 2-yr period 1930–1931 holding second place, and a drought in 1903–1905 holding third place for long periods. The year 1925 was the most critical single year for storage requirements in this area and is probably controlling, even when compared with the longer periods, for regulation resulting from multi-purpose objectives. However, if operations were for maximum power production, the longer periods would probably be controlling. This is mentioned to call attention to the fact that what may be considered as a critical drought with one objective in view may be defined quite differently for other objectives.

A similar argument might be applied to floods. Regulation which might not be fully effective in a maximum flood would certainly affect the frequency of occurrence of lesser floods as well as their magnitudes.

The important effect of broadening federal water policies with respect to both droughts and floods is to lessen their damages by adequate planning on a large scale, beyond the ability of private capital or private objectives to accomplish. Since federal planning should accomplish as many social benefits as possible, many objectives should be included and the necessary compromises made between them. In the TVA this is done through the extensive use of operating rule curves for all projects, modified from time to time as experience is gained. Herein lies one of the important jobs for the engineer, mentioned by the author.

Any mention of the multi-purpose objectives of federal agencies, in the case of southern projects in particular, should include that of malaria control. The TVA, in cooperation with the U. S. Department of Public Health and local agencies, has worked on this problem from the beginning of its activities. The creation of large bodies of water where none existed previously, with associated problems of proper beach drainage and control of vegetation along the shores, places the responsibility for controlling the breeding of mosquitos directly upon the federal agency that developed the project. It is not a minor problem.

One problem that will offer increasing difficulties in its solution is that of coordinating the work of the various federal agencies engaged upon water control and development, to prevent duplication of effort; and to establish procedures for the exchange of experience data and engineering information, and perhaps even of personnel at a time when it would be most helpful. The centralized control that is so often suggested as suited to a federal Public Works Department is directly opposed to the benefits obtainable under de-centralized agencies working closely with local state agencies, the people and institutions most affected, but with proper federal checks and controls. The engineering profession could be helpful in determining the more efficient administrative theory.

If the second scheme is adopted ultimately, it will give rise to a further problem—how to make the experience and improved techniques of one agency promptly available to another. Publication of technical information is not the entire answer because frequently it is too long delayed; it is not distributed or made available where it might be most helpful either because of cost or not knowing where the need exists. There is too much published now for any one man to review thoroughly along with his active work. Engineers frequently are not interesting and concise writers; and some of the busiest men, whose ideas and experiences might be of the greatest value, cannot or will not give the necessary thought and time required to the preparation of a paper or book along with their required daily work. Perhaps, too, progress and changes are sometimes so rapid that some engineers hesitate to commit themselves in print. There are a few who do not wish to give away their "stock in trade"—a very mistaken idea, professionally.

Perhaps committees in federal engineering groups could be formed to function something like those in the former National Electric Light Association. Annual summaries of progress and experience might be issued on classified subjects, preceded by a comprehensive review of background material. If this procedure proved successful in private practice, it could be made equally so among federal agencies. The National Resources Planning Board might be the means of accomplishing this end.

James S. Sweet,[14] Assoc. M. Am. Soc. C. E.—A few papers have been written in the past describing hydraulic activities of the government; but none attempted to relate influences of social events and natural phenomena to the federal water policies. From this standpoint the paper by Mr. Hoyt occupies a unique place in the literature on the subject. Not only is the description interesting, but it also clarifies sometimes unexplainable tendencies of the national legislation in the hydraulic field. Like other writers on this subject, the author fails to indicate weak spots of the national water policy, or to offer some constructive criticism. Even the restrictions of a federal position would not bar such criticism, if it is not malicious.

Throughout his paper the author mentions various government departments in which hydraulic or hydrologic activities exist. To a layman this fact gives reason to believe that all these activities are, or could be, coordinated. Unfortunately, this fact in itself is a sign of inefficiency, for, under the law, the jurisdiction over these activities is given to the respective departments where they are placed. This makes coordination difficult. Hence, there is much duplication and delay. An attempt toward a coordinated action was made by appointment of the Water Resources Committee of the National Resources Planning Board. However, this committee has no administrative powers; and its voice, although often speaking truth and wisdom, is unheard by those to whom it is directed.

---

[14] Regional Hydrologic Engr., U. S. Weather Bureau, Flushing, N. Y.

Placement of all hydrologic activities of the federal government in one bureau would be impracticable under the present circumstances. As an alternative, creation of a hydraulic coordinating joint committee seems quite feasible. This committee should consist of the executives of all branches of the government dealing with hydraulic works and hydrologic data. It should have a revolving chairmanship. It should act not only in the advisory capacity, but should also have executive powers. This would be facilitated by the fact that the head of each agency involved would serve on the committee and be its chairman at one time or another.

This joint committee should fill in gaps of inadequacy, eliminate overlapping activities, and coordinate existing and planned work of all hydrologic agencies, thus promoting efficiency and economy.

J. L. CAMPBELL,[15] M. AM. SOC. C. E.—The federal water policies developed since 1930 constitute one phase of a course of the federal government away from that American way of life which rests upon and is sustained by private initiative and enterprise toward some form of paternalism wherein, eventually, the conception that government is the servant of the people would perish, and the people would become dependents upon and servants of government. That is a momentous issue raised by some of the policies of the new order known as the New Deal.

In the first decade of such departure, beginning in 1932, certain phases of the broad issue indicated came to the fore in attempted regimentation of some of the economic life of the people by certain programs of the National Industrial Recovery Administration and the Agricultural Adjustment Administration—creatures of the new order—wherein it became evident that the people involved would not unanimously and completely voluntarily accept and comply with said programs, and that, consequently, basic objectives of the new order could be brought to full fruition only by dictatorial compulsion of all the people concerned. The clear implication of that situation is that certain ways of life in the new order could be made completely effective and successful only by government by dictatorship. In substance, that issue was brought to the Supreme Court of the United States, and the Court set up a bar against dictatorship; but that does not finally dispose of the general issue. Since that decision, the personnel of the Court has undergone an unprecedented and revolutionary change.

The activities to date of the Tennessee Valley Authority point to elimination or subordination of private initiative and enterprise and substitution of government ownership and operation. Similar implications lie in the Columbia Basin Project—the Grand Coulee extravaganza—and in other projects of the new order.

In general, projects coming to life under the federal water policies have a common characteristic vividly illustrated in Grand Coulee Dam which came to the Congress as an hydroelectric project asking for only $65,000,000—a modest New Deal sum. Then, like the beanstalk in "Jack and the Beanstalk," this project grew rapidly into the "stratosphere" and is now approaching completion as a multiple-use project costing nearly $400,000,000. This project is without the economic justification upon which private initiative and enterprise must rest in expenditure of money. Such projects have helped mightily in doubling the national debt of 1930.

---

[15] Chf. Engr., Northwestern Pac. R. R. (*Retired*), Oakland, Calif.

The Grand Coulee project includes proposed reclamation of more than a million acres of desert land lying above the high-water line of the reservoir created by the dam. This requires lifting the water for irrigation several hundred feet by hydroelectric power generated at the dam. This makes Grand Coulee reclamation costly and beyond the resources of the farmers. That land can be so reclaimed and farmed only if the federal government carries for the farmers a large part of the financial load. The resulting cost of food and clothing materials so produced will be above like costs in the Mississippi valley and the United States in general.

Grand Coulee reclamation was put forward and appropriations therefor were made during the time when the federal government was proclaiming an alleged overproduction of farm products, was putting the farmers into strait jackets, and was expending millions of dollars in retirement of farm lands from production for the purpose of reducing agricultural products. The barns and granaries of the country are still overflowing with farm surpluses.

Grand Coulee illustrates extremes to which public appropriations and expenditures run under compulsion of political and other pressure groups in the unusual events of the federal water policies. It is also indicative of what comes out of the whole of the new-order philosophy. Now, more than ever, unnecessary or deferable expenditures should cease during the war.

Those who support continuance of such expenditures allege that projects of the kind indicated are necessary to the war program because of the hydroelectric power which they would provide. Accordingly, immediate authorization of construction of the St. Lawrence Seaway—a five hundred million dollar project—is urged, notwithstanding the fact that several years would elapse before power would flow from it.

If power for the war is lacking, the lack should be eliminated in the shortest way possible. Therein, time rather than cost is most vital. The quickest way is by construction of steam plants at points of power consumption. Generally, first cost of steam power is far less than cost of hydroelectric power. Moreover, in most of the war power centers of the country, there would be little difference in over-all costs of construction and operation as between up-to-date steam plants and hydroelectric plants. Finally, it would be difficult indeed for the enemy to find and destroy a multitude of relatively small steam plants, and comparatively easy to locate and destroy a few great hydroelectric plants.

Is there such lack of patriotism that pet schemes dressed in the guise of war need are delaying and crippling war effort?

A general effect of some new-order policies is discouragement of self-reliance, initiative and enterprise, and encouragement of dependence upon government for social security. That is not an American, or a healthful, trend.

Another regrettable development is the great expansion in number and size of governmental functions and agencies resulting from new-order policies and activities, upon which it is now necessary to superimpose the vast war work organizations of the government. The President suggests that many people in Washington, D. C., not in government service, should move out to give the government elbow room. Liquidation of a large number of new-order agencies would be a better remedy.

Of course, America must move forward; but she should so move in the right way, under the Bill of Rights of the individual in the charter of American liberty. A new order should not be condemned, or swallowed whole, merely because it is new. By its fruits, it should be judged. By that measure, the new order herein under criticism is partly good and partly bad. To be worthy to endure and able to serve sanely and beneficently, this new order, to the extent that it may be afflicted by them, must be purged of faults and dangers, such as are indicated in this critique.

Turning to the engineering and construction work of building the projects fathered by the federal water policies originated since 1930, the picture is a happy one wherein superb engineering design and direction and marvelous construction work have created sound and efficient structures of unprecedented magnitude and highest excellence. The engineering profession and the construction art may look in great complacence upon such achievements; but such structures are not, in themselves, justification for their existence.

Yes, under the federal water policies, there is a horn of plenty of "unusual events."

DAVID J. GUY,[16] ESQ.—Without oversimplification, the author has isolated the germs of a revolution that is taking place in the policy of the United States with respect to water resources. The combination of circumstances cited—one physical, one economic, and one altruistic—is producing (in fact has already produced) a complete reorientation in the water-utilization program. No one can challenge the fact that the decade 1930–1940 was characterized by unusually large and destructive floods. The author's statement that similar climatic and hydrologic conditions have "probably" not been exceeded during the past century is accepted.

However, for a proper evaluation of this condition as one of the combination of circumstances shaping national policy, the reader requires a fuller historical background. The impact of unusual climatic and hydrologic conditions upon national life depends upon the character of national life at the time of their occurrence. To illustrate, science reveals that there is no sound—there are only sound waves—if there is no ear to intercept the sound waves. It is so in large degree with the occurrence of unusual floods. Population density, economic wealth, and encroachment of structures upon the natural flood plains and channels of rivers are determining factors in appraising flood effects and therefore the wisdom or unwisdom of any given flood-control policy.

When levee construction along the Mississippi River began at New Orleans, La., in 1717, small earthen dikes from 4 ft to 6 ft high were all that was necessary to afford protection from floods. At that time this appeared to be a wise flood policy, although future years proved that these same levees created a bottleneck that accentuated flood dangers; and, as other sections along the river above New Orleans built dikes, robbing the river of its flood plain, the race for higher and higher levees became a flood-creating flood-preventing device, robbing Peter to pay Paul.

---

[16] Hydr. Engr., Natural Resources Dept., Chamber of Commerce of the United States, Washington, D. C.

The passage of the Swamp-Land Act in 1850 established another "water-regulation policy" and that, from the backsight of today, had many unwise features. The author's paper deals with land and water, and it may also be pointed out that numerous recent land-policy discussions, appearing in print, have cast much unjust criticism at the early land-settlement policies of this country, particularly the Homestead Act. Fairness requires that the early policy makers in the United States, dealing with land and water, be credited with enacting laws and putting into effect policies deemed wisest by them in the light of the problems of their time. Even today there are lawsuits in California because of efforts to prevent river floods that overflow and replenish the ground water supply of the lower plains area.

This subject of national water policy calls for a more extensive plotting of points and circumstances before anyone can indicate a trend line with confidence. An old farmer once said he never had any trouble getting two fence posts in line, but when he had three he ran into difficulty.

Land and water policies should be founded upon scientific and engineering inquiry. Unfortunately, "The impact of an economic crisis," to which the author refers (see "Introduction"), has been more persuasive with the legislative policy makers. It is questionable whether a federal water policy shaped by the ebb and flow of unemployment can be judged engineeringly sound. It is also questionable whether the use of soil and water conservation as a Constitutional peg for economic adjustments in agriculture should be admitted by the engineering profession as a factor in shaping national water policies. This is not to say that the engineer should avoid all consideration of matters beyond those that are technical and immediately "profitable." The danger is that any water policy may be literally pulled to pieces for no other purpose than to make legal and Constitutional pegs on which to hang a variety of new social and political philosophies.

The current water policy is enmeshed in the "shelf of projects" that has been built up, awaiting the "go" sign when jobs are needed after the war ends. Many of these projects are for the purpose of conserving and using water resources. As experience gained in the past decade has shown, economic soundness does not necessarily control the order of development when the objectives sought lie outside the bounds of an integrated water policy.

Emergency relief through make-work projects was made readily acceptable by the generous use of the federal treasury. Appropriations through the various emergency relief acts of the period 1935–1942 exceed $15,000,000,000. Never before has the United States accepted the lure of debt and borrowing as witnessed in the decade 1930–1940, reviewed in the author's paper on water policy.

This decade witnessed generous use of federal loans and grants to states and municipalities for the development of water resources. The long-established policy of the Army Engineer Corps that required local contributions toward the cost of river-improvement structures was seriously threatened by the 1936 Flood Control Act, and was practically eliminated by the 1938 Flood Control Act. The complete elimination of local contributions tends to make flood control a "pork-barrel" proposition. Heretofore, the willingness to share the cost was the best index of a local need of flood control. The principle, rather than the amount, of local contribution is important. It may be, as the author states, that the great losses during the 1930–1940 decade from floods and droughts "made a deeper impression on policy makers, than ever before" (see "Introduction"), but public acceptance was achieved largely because of the federal Santa Claus. Here is one obvious reason "for the rapid transition of a wide popular movement or belief into an active action program" of which the author speaks (see "Introduction"). Here is a kind of inverted "dollar diplomacy." Dollar policy making carried with it certain objectives and created certain obligations. This has long been the situation growing out of various forms of federal aid—to wit, the beneficiary surrenders something, usually a measure of local control.

It is no surprise, therefore, that many new federal agencies were created—some by Congress, some by Executive Order—to exercise the rights and powers yielded by states and communities. Widespread federal planning came into vogue. It now embraces every possible land and water use, and extends from the smallest mountain stream to sea level. The Nation is now in a period of intensive federal water-policy making accompanied by a rapid decline in state and local control.

The extension of federal water policy does not stop at planning. It is being projected into the fields of operation and management, prompted, at times, by political rather than engineering considerations. Again the "Constitutional peg" comes into play. The licensing policy of the Federal Water Power Act established in 1920 has been abandoned for direct federal construction of water-power plants and federal marketing of the energy generated. This latter, a marketing phase, is still in a much muddled state. The political desire for public power has been of equal or greater influence in shaping present water-power policies than any circumstance of the "1930–1940 flood situation" to which the author refers.

"Multiple-use projects" has become a slogan which has political as well as engineering significance. This multiplicity of uses has greatly extended the field of federal participation and has served to divest states of much of their control of water resources. "Multiple use" presumes an ability on the part of planners to make fine economic adjustments in water-use values that, from an engineering approach, can be little more than wishful thinking. Take, for example, the question of allocating cost between flood-control and water-power benefits. Army engineers used to measure allowable flood-control expenditures by capitalizing flood losses. The best that can be said for this practice is that it served to indicate the relative importance of the regions damaged. The need for flood protection, and therefore the amount of expenditures, is determined by the measure and extent of the fear the endangered people feel, due to the recurrence of floods. It is this fear that generates the pressure on the members of Congress, state legislators, and the "city fathers" to appropriate the money for flood control. The methods of control are for the engineers to determine.

With water power, the former practice was to measure its economic value by comparison with the cost of steam power. The current policy seems to be to allocate to power only such a share of the capital investment as will make government power "cheap" in comparison with prevailing prices of private utility companies. This might be an acceptable policy if its object were for no other purpose than to assure the disposal of the government's power by-product at multiple-purpose projects. The trend of the policy, however, is to undertake federal dictation of retail rates for electric service, a long recognized state function.

The "multiple-use" policy has not developed into a true water-conservation policy such as was envisioned 40 years ago by such men as George Maxwell and the late Frederick H. Newell, M. Am. Soc. C. E. The nearest approach to water-conservation policy in recent years is found in the program for upstream development furthered by the Wheeler-Case Act and the Taylor Grazing Act. This departure in water policy, so well presented by the author, stands in marked contrast to the earlier flood-control and navigation-improvement policy which was so rigidly confined to the lower reaches of major streams.

The stimulus to fact finding and hydrologic research, which has come about not only through the demand for more and better data but also through the generous allocation or appropriation of funds to these ends, is a valuable part of the new policy from the engineering standpoint. It is to be hoped that the politicians and planners eventually will be guided more and more by this research than by politics and social philosophy.

The writer concurs with the author's concluding expectation that only future experience can show the soundness or unsoundness of the prevailing water policy and, therefore, the need for modifications. Only by gearing the planning to a practical, and, therefore, immediate future can the needs of today and the probable needs of tomorrow be balanced with the greatest measure of justice and practicability. Such planning, to be of maximum value, requires constant adjustment in the light of social and economic changes and, one may well add, in the light of what the author describes as abnormalities in climatic and hydrologic conditions. In its very best sense politics must be a matter of issues; and national water policies, in regard to both practice and planning, should be based upon economic and engineering facts and should be free of such issues.

ALBERT S. FRY,[17] M. AM. SOC. C. E.—An excellent summarization of the developments and interrelations of federal water policies during the decade between 1930 and 1940 is presented by the author. The paper is particularly noteworthy because it presents a vast amount of material in condensed form of a readable length.

Perhaps somewhat more significance should be placed on the great flood of 1927 in the Mississippi Valley as influencing a change in federal water policies, and the revolution in federal water policies might well be dated from that time rather than 1930. It was the great flood of 1927 that really demonstrated that flood control is a national problem far too big for local interests even in good times. The federal legislation that resulted in 1928, following this flood, recognized flood control for the first time as a national responsibility. Although levees had been built for many years previously along the Mississippi River, this work had been done under the guise of navigation rather than flood control. The studies of the Army engineers, embodied in the Jadwin plan, and later developments showed that the ultimate flood protection of the Mississippi Valley required something more than levees, and a comprehensive reservoir plan was developed for the Ohio River Basin. This plan was a stepping stone to the flood control acts of 1936 and 1938.

[17] Head Engr., Hydr. Data Div., TVA, Knoxville, Tenn.

The creation of the TVA in 1933 marked not only the inception of a multiple-use project by the federal government, as the author states, but it also created for the first time a complete watershed development project with all phases of that development under one federal agency. As the author has indicated, other federal legislation has provided for cooperation between various governmental agencies, such as the Corps of Engineers and the Department of Agriculture, but only in the TVA has the complete water control of a large drainage basin, including water control both on the land and in the streams, been authorized and established under one agency. The success of this method of handling the water problems of a region has resulted in legislation being introduced into Congress to create other similar authorities.

This completely unified type of organization has facilitated the planning of water-control projects, utilizing the contributions of various sciences such as hydrology, forestry, and agriculture, and appears to have distinct advantages in the development of a complete water-control plan for a region over the more cumbersome procedure of planning by two or more separate governmental agencies, each jealous of its own particular field in the culmination of the final plan. Integral with the TVA type of organization is a recognition of the basic hydrologic information needed for complete water-control planning from all standpoints and maximum utilization of the data by the several sciences involved. Illustrative of this may be mentioned the pioneer work of the TVA in the extension of the network of rainfall stations throughout the Tennessee Valley, particularly those on higher altitudes for which no accurate information as to rainfall amounts and intensities previously existed.

A most beneficial result of recent federal water policies has been the development of closer cooperation between various government agencies concerned with water projects and the recognition of the interrelationships of the interests of these several agencies in specific problems. The TVA, for example, although organized to handle completely the water problems of its region has, from its beginning, recognized the value, and pursued a policy, of close cooperation with existing governmental agencies to avoid duplication of effort. Stream-gaging work for the TVA is done by the U. S. Geological Survey with which there has been a close and most satisfactory cooperation throughout the life of the Authority. This relationship has resulted in an increase in the scope and importance of the work of the Survey in the Tennessee Valley region. Where formerly stream-gaging stations were operated in the Tennessee Valley, and the results published years later in *Water-Supply Papers*, immediate problems of planning and construction of TVA projects have resulted in stream-flow information being obtained from an increased number of stations and kept up to date for the day-to-day needs of the Authority. The making of stream-flow measurements below a large dam on the Tennessee River in the morning to be used in connection with operations in the afternoon is quite different from collecting records to be worked up and published years later.

Another example of a cooperative relationship is that between the Weather Bureau and the TVA with respect to weather forecasting, which is utilized in the operation of the many reservoirs in the Tennessee Valley. This unique arrangement provides the TVA with weather forecasts twice daily or oftener and the TVA in turn forecasts river stages throughout the Tennessee Valley, the information on both weather and rivers being given to the public in the form of a cooperative daily bulletin. It was recognized by Weather Bureau officials that, although the Bureau is required by law to forecast river stages throughout the United States, since the TVA necessarily had to do much more detailed forecasting in connection with its reservoir operations, it would be inefficient for the Weather Bureau to duplicate this work.

W. G. Hoyt,[18] M. Am. Soc. C. E.—It was not, and is not, the intent of the writer to criticize any present water function or policy; the paper is factual and philosophical and not critical. Therefore, he will not attempt especially to point out "weak spots" as suggested by Mr. Sweet. As emphasized in the paper and discussions, water policies, at any one time, have depended in some immeasurable degree on climatic, economic, and social circumstances. When conditions change, policies respond. What may seem valid and constructive criticism currently, often looks ill-considered in retrospect. From the viewpoint of peacetime, Mr. Campbell may be justified in holding that federal water policies developed since 1930 "constitute one phase of a course of the federal government away from that American way of life which rests upon and is sustained by private initiative" and that many projects were extravagant and without economic justification.

From the point of view of peacetime, no one can yet say positively whether the projects were generally worth the cost. It is certain, however, that water planning and development have stood the Nation in good stead during the present emergency. By providing major sources of energy, many so-called extravagant developments have been the very foundation on which this country's enormous industrial expansion for war has been based. Factories were kept in operation during periods of depression, turning out equipment for use on what was often then considered "made work" incident to water, soil, and conservation projects. As a result, when it became necessary to establish army and navy bases in the four corners of the world, mobile equipment was available; many factories were tuned to produce and expand if necessary; and what was more important, many persons trained for peaceful employment in the Public Works Administration, Work Projects Administration, Civilian Conservation Corps, and other organizations, stepped into war activities without losing stride. This fortunate result is not necessarily attributable to the planners; nor does it follow that because peacetime policies proved their worth in wartime they were or are necessarily the best that could be devised. In fact, much evidence seems to indicate that major modifications in water policies are desirable.

---

[18] Hydr. Engr. (Prin.), Water Resources Branch, U. S. Geological Survey, Washington, D. C.

The discussions by Messrs. Sargent, Wood, Guy, and Fry have added greatly to the treatment and development of the subject as a whole through inclusion of text and references outlining events and circumstances having to do with the water policies prior to the decade under consideration. The paper and discussions outline many of the events and circumstances by which the nation has arrived at its present water policy, a policy under which billions of dollars have been spent by federal, state, and local interests "without the benefit or direction of a consistent national water policy designed to produce the optimum coordinated development in the interests of all."[19] Now the Nation is at war, and until this war is won, there will be little modification of present policies. After the war is over, if policy makers agree with the National Resources Planning Board that "the present uncoordinated administration of laws and policies * * * cumulatively have not been sufficiently effective in producing properly balanced development of our resources for the people of the Nation, for the people of the regions or even for the people of certain individual basins,"[19] then they may well review some of the pertinent points brought out in the paper and discussions, parts of which are quoted herein.

Future policy makers must decide whether or not the best objectives will be accomplished by following the advisory leadership of the Water Resources Committee of the National Resources Board; or whether a similar committee should be vested with sufficient authority and so organized as to enable it to coordinate and direct future water policies; or whether the creation of a "hydraulic coordinating joint committee," as suggested by Mr. Sweet, "with a revolving chairmanship and executive powers" would be more appropriate. They must decide whether a basin project with all phases of that development under one federal agency, embracing a complete, unified type of organization for the planning of water-control projects and utilizing contributions of various sciences, such as hydrology, forestry, and agriculture, has more advantages than the procedure of planning by separate governmental agencies with separate functions and with Nation-wide scope, even though the planning is guided by a central committee.

In other words, should there be a Nation-wide group of authorities similar to the Tennessee Valley Authority, the diversified activities of which have been so clearly outlined by Messrs. Wood and Fry, or should developments for irrigation, power, flood control, and land-use continue to be administered by separate organizations, federal or state, the policies of which are fixed by law, or a combination of both? Should such groups (as Mr. Guy questions) embrace a federal water policy "shaped by the ebb and flow of unemployment" and use "soil and water conservation as a Constitutional peg for economic adjustment?" Future policy makers should avoid the danger that "any water policy may be literally pulled to pieces for no other purpose than to make legal and Constitutional pegs on which to hang a variety of new social and political philosophies." They should keep in mind that unusual meteorologic and hydrologic events, such as described in the paper, will recur and that in all probability the shaping of future policies will be affected by the occurrence and magnitude of these events. They should determine "whether the complete elimination of local contributions tends to make flood control a pork barrel proposition" or whether the present policy with respect to local contributions for irrigation development is the more equitable. They should determine whether or not the creation of many new federal agencies "to exercise the rights and powers yielded by states and communities" is wise and whether or not a federal water policy should be projected further into the fields of operation and management, "prompted, at times, by political rather than engineering considerations." These and many other pertinent questions raised in the discussions will necessarily have to be considered by those who will guide future policies.

EFFECT OF VARIATION OF ELASTIC CHARACTERISTICS ON STATIC UNKNOWNS

By A. Hrennikoff,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. A. H. Finlay, Stefan J. Fraenkel, Joseph A. Wise, and A. Hrennikoff.

Synopsis

As is well known, the values of statically indeterminate quantities are influenced by the elastic characteristics of the structure, such as cross-sectional areas of compression and tension members, moments of inertia of flexural members, and moduli of elasticity. The actual magnitudes of these elastic characteristics are likely to differ somewhat from the values assumed in analysis because of inaccuracies and accidents of manufacturing and construction, and these may result in deviation of the actual stress values from the quantities used in the design. A proportional change in an elastic characteristic in different parts of the structure in most cases will not affect the values of static unknowns, but a random variation of cross-sectional area, moment of inertia, or modulus of elasticity from point to point may influence the results considerably, depending on location, magnitude, and sign of the variation.

These discrepancies or variations of the elastic characteristics are not always negligible. Thus, a ¼-in. deficiency in the thickness of a 12-in. reinforced-concrete slab causes a decrease of more than 6% in the moment of inertia of the member. The modulus of elasticity of steel is not likely to differ more than 3% from the usual value of 29,000,000 lb per sq in., but the modulus of concrete is subject to large variations. Thus, in tests of full-sized reinforced-concrete rigid frames, conducted in 1938,[2] the values of the modulus of elasticity of concrete specimens cut from different parts of the same frame varied from 3.7 to 5.9 million pounds per square inch—that is, the extreme values differed from the average of 4.8 by 23%. In conditions of actual practice these variations are likely to be even greater.

Note.—Published in January, 1942, *Proceedings*.

This paper presents a general method of determining the greatest possible variation in the magnitude of a statically indeterminate quantity caused by most unfavorable distribution of assumed legitimate variations in the elastic characteristics.

NOTATION

The letter symbols used in this paper are defined where they first appear and are assembled for convenience of reference in the Appendix.

MAXIMUM VARIATION OF A STATICALLY INDETERMINATE QUANTITY

Before proceeding with the mathematics of the problem, it is necessary to state definitely what variations of the elastic characteristics should be considered legitimate. It will be assumed that an elastic characteristic may deviate from its theoretical value ϵ anywhere on the structure by an amount not in excess of $i\,\epsilon$, in which i is a small, theoretically infinitesimal, quantity. The actual values of the assumed variations and their signs at different points of the structure will be selected in such a manner as to make the variations of the statically indeterminate quantity in question the greatest. A different statically indeterminate quantity will require a new arrangement of variations of the elastic characteristic, staying within the limits $\pm\, i\,\epsilon$ anywhere on the structure. It will be assumed also that the modulus of elasticity E of flexural members will vary in such a manner as to have the same values in the planes normal to the axis of the member. Thus the member will consist of short rectangular blocks, cut by sections normal to the axis, with E varying from block to block but constant in the same block. This assumption that E is constant in each block is more severe in its effect on the variation of the statically indeterminate quantity than the assumption that it changes across the axis of the member, since a given change in E over the entire block modifies flexural deformability of this particular element of the structure by a greater amount than an equal change in E extending only over a part of the block.

Consider a structure with an arbitrary number of statically indeterminate quantities acted upon by a given set of loads. For definiteness only three static unknowns X_a, X_b, and X_c will be used in the derivation, although the formulas derived will be applicable to any number of unknowns. The equations of continuity from which the unknowns are to be found may be written in the form:

$$\left.\begin{aligned} X_a\,\delta_{aa} + X_b\,\delta_{ab} + X_c\,\delta_{ac} + \delta_{ao} &= 0 \\ X_a\,\delta_{ab} + X_b\,\delta_{bb} + X_c\,\delta_{bc} + \delta_{bo} &= 0 \\ X_a\,\delta_{ac} + X_b\,\delta_{bc} + X_c\,\delta_{cc} + \delta_{co} &= 0 \end{aligned}\right\} \dots\dots\dots\dots\dots (1)$$

In Eqs. 1 the familiar quantities δ refer to the basic statically determinate structure and represent the movements of the points of application of the static unknowns in the directions of the unknowns. The first subscript always indicates the point that moves, and the second subscript, if it is o, indicates that the movement is caused by the actual loads, and, if it is a, b, or c, signifies that the movement is caused respectively by any of the forces $X_a = 1$, $X_b = 1$, or $X_c = 1$. Thus, δ_{ab}, for example, represents the movement of the point of application of X_a in the direction of X_a, caused in the statically determinate structure by the force $X_b = 1$; also δ_{co} represents the movement of the point of application of X_c in the direction of X_c caused in the statically determinate structure by the actual loading. By the law of reciprocity $\delta_{ab} = \delta_{ba}$, with two similar equalities for the other values of δ.

By solving Eqs. 1,

$$X_a = -\frac{D_{1a}\,\delta_{ao} + D_{2a}\,\delta_{bo} + D_{3a}\,\delta_{co}}{D} \qquad (2)$$

with two similar expressions for X_b and X_c.

In Eq. 2, D is the determinant composed of the coefficients of the three unknowns in Eqs. 1; and D_{1a}, D_{2a}, and D_{3a} are the corresponding minor determinants composed of the coefficients of the unknowns other than X_a—that is:

$$D = \begin{vmatrix} \delta_{aa} & \delta_{ab} & \delta_{ac} \\ \delta_{ab} & \delta_{bb} & \delta_{bc} \\ \delta_{ac} & \delta_{bc} & \delta_{cc} \end{vmatrix} \qquad (3)$$

and

$$\left.\begin{aligned} D_{1a} &= \begin{vmatrix} \delta_{bb} & \delta_{bc} \\ \delta_{bc} & \delta_{cc} \end{vmatrix} \\ D_{2a} &= \begin{vmatrix} \delta_{bc} & \delta_{cc} \\ \delta_{ab} & \delta_{ac} \end{vmatrix} \\ D_{3a} &= \begin{vmatrix} \delta_{ab} & \delta_{ac} \\ \delta_{bb} & \delta_{bc} \end{vmatrix} \end{aligned}\right\} \qquad (4)$$

The minor determinants D_{1b}, D_{2b}, etc., entering the expressions for X_b and X_c, are formed in a manner similar to Eq. 4.

It will be recalled that the various expressions δ represent integrals involving the elastic characteristics. Thus, in structures consisting of flexural members only,

$$\left.\begin{aligned} \delta_{ab} &= \int \frac{m_a\,m_b}{E\,I}\,ds \\ \delta_{ao} &= \int \frac{M_o\,m_a}{E\,I}\,ds \end{aligned}\right\} \text{(etc.)} \qquad (5a)$$

In Eq. 5*a*, I is the moment of inertia; and M_o, m_a, and m_b signify the bending moments developed in the basic statically determinate structure: By the given loading; by the force $X_a = 1$; and by the force $X_b = 1$, respectively. Likewise, in structures made up of the direct-stress members only:

$$\left.\begin{aligned} \delta_{ao} &= \sum \frac{N_o\,n_a}{E\,A}\,L \\ \delta_{ab} &= \sum \frac{n_a\,n_b}{E\,A}\,L \end{aligned}\right\} \text{(etc.)} \qquad (5b)$$

In Eq. 5*b*, L is the length of a structural member; and N and n are the direct stresses in the members corresponding to the same loading conditions as the moments M and m in Eq. 5*a*.

Suppose now that one of the elastic characteristics, such as the modulus of elasticity E, increases by an infinitesimal increment dE in a block of the length ds in any part of the structure. This causes differential increases in δ-values —$d\delta_{ao}$, $d\delta_{ab}$, etc. Since Eqs. 1 still hold for the structure, with the elastic properties modified in this manner, the values of static unknowns must readjust themselves to the new δ-values, and their corresponding increments dX_a, dX_b, etc., may be found by taking the total differentials of Eqs. 1 and solving the resultant equations for these increments. By this differentiation:

$$\delta_{aa}\, dX_a + \delta_{ab}\, dX_b + \delta_{ac}\, dX_c + (X_a\, d\delta_{aa} + X_b\, d\delta_{ab} + X_c\, d\delta_{ac} + d\delta_{ao}) = 0 \quad (6)$$

with two other similar equations.

These three equations can be solved for the unknowns dX_a, dX_b, and dX_c since all values of X and δ are known from Eqs. 2 and 5, and values of $d\delta$ are fixed by the assumed variation in the elastic characteristic.

Next, introduce the new functions:

$$\left.\begin{aligned} \Delta_a &= X_a\, \delta_{aa} + X_b\, \delta_{ab} + X_c\, \delta_{ac} + \delta_{ao} \\ \Delta_b &= X_a\, \delta_{ab} + X_b\, \delta_{bb} + X_c\, \delta_{bc} + \delta_{bo} \\ \Delta_c &= X_a\, \delta_{ac} + X_b\, \delta_{bc} + X_c\, \delta_{cc} + \delta_{co} \end{aligned}\right\} \quad (7)$$

in which the X-quantities are assumed constant and equal to the values determined from Eq. 2; and the δ-quantities, defined by Eqs. 5, are thought of as functions of the elastic characteristics E and I, considered as variables. The new expressions Δ will be recognized as the left-hand side parts of the basic Eqs. 1, and, although they vanish for the original δ-values, they are generally different from zero for the modified values of δ corresponding to new and variable values of E and I.

By differentiation of Eqs. 7

$$d\Delta_a = X_a\, d\delta_{aa} + X_b\, d\delta_{ab} + X_c\, d\delta_{ac} + d\delta_{ao} \quad (8)$$

with two similar expressions for $d\Delta_b$ and $d\Delta_c$. Substitution of these expressions in Eqs. 6 converts the latter into the following form:

$$\left.\begin{aligned} \delta_{aa}\, dX_a + \delta_{ab}\, dX_b + \delta_{ac}\, dX_c + d\Delta_a &= 0 \\ \delta_{ab}\, dX_a + \delta_{bb}\, dX_b + \delta_{bc}\, dX_c + d\Delta_b &= 0 \\ \delta_{ac}\, dX_a + \delta_{bc}\, dX_b + \delta_{cc}\, dX_c + d\Delta_c &= 0 \end{aligned}\right\} \quad (9)$$

A marked similarity may be noted between these equations, serving for the determination of the variations dX_a, dX_b, and dX_c, and the basic Eqs. 1, serving for the determination of the static unknowns X_a, X_b, and X_c. The expressions for dX_a, etc., may be written by analogy with Eq. 2:

$$dX_a = -\frac{D_{1a}\, d\Delta_a + D_{2a}\, d\Delta_b + D_{3a}\, d\Delta_c}{D} \quad (10)$$

with similar expressions for dX_b and dX_c. The determinants D, D_{1a}, etc., have the same significance in these expressions as in Eq. 2.

Eq. 10 determines the value of a small variation in the static unknown X_a produced by an assumed variation in an elastic characteristic resulting in corresponding variations in the values of δ and Δ. When the modulus of elasticity E receives an increment dE anywhere along an infinitesimal length ds of one of the members comprising the structure, the changes caused in different values of δ may be exemplified by the following expression for one of them:

$$d\delta_{aa} = d\left(\frac{m^2_a}{E\,I}\,ds\right) = -\frac{m^2_a\,ds}{I}\,\frac{dE}{E^2} \qquad \text{(11)}$$

If $\frac{dE}{E} = i'$, a small, theoretically infinitesimal, quantity, the following equation results:

$$d\delta_{aa} = -\,i'\,\frac{m^2_a\,ds}{E\,I} \qquad \text{(12}a\text{)}$$

In Eq. 12*a* the variable quantities m_a, E, and I refer to the element of structure whose modulus of elasticity E has undergone the change.

If the variation of E occurs over a finite part, or even over the entire structure, the expression for $d\delta_{aa}$ becomes:

$$d\delta_{aa} = \int -\,i'\,\frac{m^2_a\,ds}{E\,I} \qquad \text{(12}b\text{)}$$

in which the integration is extended over the appropriate lengths of the members of the structure. Variations of other values of δ have similar expressions. The term i' should be considered at the present stage as a quantity variable along the structure but, naturally, the same in all values of δ for the same length element ds.

Substituting Eq. 12*b* in Eq. 8, and combining several integrals into one, the following expression results for $d\Delta_a$:

$$d\Delta_a = \int -\,i'\left(X_a\frac{m^2_a}{E\,I} + X_b\frac{m_a\,m_b}{E\,I} + X_c\frac{m_a\,m_c}{E\,I} + \frac{M_o\,m_a}{E\,I}\right)ds \qquad \text{(13)}$$

Two similar expressions follow for $d\Delta_b$ and $d\Delta_c$.

It should be stated that if the variation in E has occurred over the entire structure, and if i' is constant, the expressions for $d\Delta_a$, $d\Delta_b$, and $d\Delta_c$ all vanish since i' appears outside of the integral signs, and the integrals themselves become the left-hand parts of the basic Eqs. 1, slightly rearranged. On the other hand, with the value of i' variable, the expressions (Eq. 13) generally do not vanish.

Substituting the expressions for $d\Delta_a$, $d\Delta_b$, and $d\Delta_c$ in Eq. 10 and combining the integrals once more, the expression for dX_a becomes:

$$\begin{aligned} dX_a = \frac{1}{D}\int i'\Bigg[\, & D_{1a}\left(X_a\frac{m^2_a}{E\,I} + X_b\frac{m_a\,m_b}{E\,I} + X_c\frac{m_a\,m_c}{E\,I} + \frac{M_o\,m_a}{E\,I}\right) \\ & + D_{2a}\left(X_a\frac{m_a\,m_b}{E\,I} + X_b\frac{m^2_b}{E\,I} + X_c\frac{m_b\,m_c}{E\,I} + \frac{M_o\,m_b}{E\,I}\right) \\ & + D_{3a}\left(X_a\frac{m_a\,m_c}{E\,I} + X_b\frac{m_b\,m_c}{E\,I} + X_c\frac{m^2_c}{E\,I} + \frac{M_o\,m_c}{E\,I}\right)\Bigg] ds \qquad \text{(14)} \end{aligned}$$

The variable term i' in this expression has been moved outside of the brackets because it has the same value in all three quantities in parentheses, at the same elements ds.

Eq. 14 can be used to evaluate the variation dX_a provided that the function i' expressing the law of variation of dE along the structure is known or has been assumed. The problem, however, is to determine the greatest possible value of dX_a.

A little thought will serve to show that, if i' is taken as a constant quantity over the entire structure, it appears as a factor outside of the integral sign, and the integral itself then vanishes, since it represents a sum of three integrals, each of which vanishes separately. This deduction is evident, of course, from general principles, because a constant i' signifies a change in E in a constant ratio over the entire structure, and such change, as has been explained, does not generally influence the values of the static unknowns. This vanishing of the integral in Eq. 14 for a constant value of i' means, of course, that the values within the brackets must be positive for some parts of the structure and negative for others. Therefore, a comparatively large variation dX_a will correspond to an assumption of a positive i' in the parts of the structure in which the values within the brackets in Eq. 14 are positive, and a negative i' in the parts in which these brackets are negative. On this assumption, the integral in Eq. 14 will represent an infinite sum of infinitesimal terms each of which is positive. Furthermore, since each of these infinitesimal terms is proportional to i', the greatest possible variation dX_a will evidently correspond to an assumption of numerically greatest value of i' (namely i), occurring over the entire structure and being positive at the points with positive values within the brackets, and negative at the negative values within the brackets. Therefore,

$$
\begin{aligned}
dX_a\,(\max) = \frac{i}{D}\int \Bigg| \Bigg[& D_{1a}\left(X_a \frac{m^2_a}{EI} + X_b \frac{m_a m_b}{EI} + X_c \frac{m_a m_c}{EI} + \frac{M_o m_a}{EI}\right) \\
& + D_{2a}\left(X_a \frac{m_a m_b}{EI} + X_b \frac{m^2_b}{EI} + X_c \frac{m_b m_c}{EI} + \frac{M_o m_b}{EI}\right) \\
& + D_{3a}\left(X_a \frac{m_a m_c}{EI} + X_b \frac{m_b m_c}{EI} + X_c \frac{m^2_c}{EI} + \frac{M_o m_c}{EI}\right) \Bigg] \Bigg|\, ds \quad \ldots\ldots (15)
\end{aligned}
$$

in which the sign | | signifies the numerical value of the expression within the brackets.

Evaluation of Eq. 15 involves a determination of the zero points of the function within the brackets by equating it to zero and by solving the resultant equation in s, exactly or approximately. The integration then is performed separately in the intervals between the terminal points and these zero points, and the numerical values of the positive and negative parts of the integral are added. The function within the brackets may also be plotted against the abscissas s, and the value of the integral may be obtained by measuring the area between the curve and the axis of s with a planimeter. In this operation the areas both above and below the axis must be taken as positive.

It will be clear from examination of Eq. 15 that the function under the integral represents a first-degree polynomial with constant coefficients with respect to the terms $\frac{M_o m_a}{EI}$, $\frac{m^2_a}{EI}$, etc. Therefore, the integration in Eq. 15 is usually no more complicated than the integrations required for a determination of various δ-values. If the axis of the structure is of a complicated shape and if the loading is complicated, or if the moment of inertia is variable, an exact integration of Eq. 15 is impossible and that formula must be replaced by a summation, a procedure similar to the usual method of determining the values of δ in a statically indeterminate analysis.

After Eq. 15 has been evaluated it is useful to state the required variation in the form

$$dX_a\,(\max) = K\,i\,X_a \ldots\ldots\ldots\ldots\ldots\ldots\ldots(16)$$

and to calculate the coefficient K representing the maximum percentage by which the value of X_a may change if the elastic characteristic is to vary by 1%.

The method of determining the most unfavorable effect of a variation of the moment of inertia I is similar to the foregoing, except that the symbols i' and i would in this case signify the ratio $\frac{dI}{I}$ instead of $\frac{dE}{E}$.

In the analysis of statically indeterminate reinforced-concrete structures it is customary to make a constant percentage allowance for steel reinforcement in the moments of inertia and to use the moments of inertia of uncracked sections. Taking $I = 1.1\,\frac{b\,h^3}{12}$ and differentiating this expression

$$\frac{dI}{I} = \frac{db}{b} + 3\,\frac{dh}{h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots(17)$$

It is reasonable to assume that the ratios $\frac{db}{b}$ and $\frac{dh}{h}$ can take any values up to the limits i_b and i_h anywhere on the structure, or in symbols

$$\left|\frac{db\,(\max)}{b}\right| = i_b; \quad \text{and} \quad \left|\frac{dh\,(\max)}{h}\right| = i_h \ldots\ldots(18a)$$

and

$$\left|\frac{dI\,(\max)}{I}\right| = i_b + 3\,i_h \ldots\ldots\ldots\ldots\ldots\ldots(18b)$$

Eq. 18*b* must be substituted for i in Eq. 15 to evaluate the maximum effect of variation in I on the value of the statically unknown quantity X_a. In barrel arches the moment of inertia may vary only by virtue of a variation in the depth h, which requires that $i_b = 0$.

It is also possible to assume that

$$|db\,(\max)| = C_b \quad \text{and} \quad |dh\,(\max)| = C_h \ldots\ldots\ldots(19)$$

in which C_b and C_h are constant numbers. In that case the ratio i' in Eq. 14 becomes variable along the structure and remains under the integral sign.

It is needless to state that the method described herein is equally applicable to structures composed of tension and compression members. In that case integrals in Eqs. 12 to 15 must be replaced by the finite sums of the terms involving the functions $\frac{N_o\, n_a}{E\,A}\,L$, $\frac{n^2_a}{E\,A}\,L$, etc.

The greatest effect on X_a of the simultaneous most unfavorable variations in E and I for the same condition of loading may be found by direct addition of the two separate effects of changes in elastic characteristics. This can be demonstrated easily by reference to the foregoing equations. By the rules of differentiation the total differential of any δ when both E and I vary is equal to the sum of the two $d\delta$'s corresponding to separate variations of E and I. Then it follows from Eq. 8 that the quantity $d\Delta$, with any subscript for the condition when E and I both vary, equals the sum of the functions $d\Delta$ with the same subscript found for the conditions of separate variations in E and I. Finally, the linear form with respect to various $d\Delta$'s of Eq. 10 for the total variation dX_a proves the required theorem of straight addition of the two separate variations dX_a.

Eq. 15 for the greatest value of dX_a is perfectly general with regard to the number of static unknowns in the structure investigated, with the exception of the structure with only one unknown, since in that case symbols for minor determinants D_{1a}, etc., become meaningless.

For a structure only once statically indeterminate, $X_a = -\frac{\delta_{ao}}{\delta_{aa}}$, which by differentiation gives

$$dX_a = -\frac{1}{\delta_{aa}}\left(d\delta_{ao} - \frac{\delta_{ao}}{\delta_{aa}}\,d\delta_{aa}\right) \ldots\ldots\ldots\ldots\ldots (20a)$$

and then, following the same logic,

$$dX_a\,(\max) = \frac{i}{\delta_{aa}}\int \left|\left(\frac{M_o\, m_a}{E\,I} + X_a\,\frac{m^2_a}{E\,I}\right)\right| ds \ldots\ldots\ldots (20b)$$

In a structure with two static unknowns, substitution of the values of determinants in Eq. 15 results in a simplified expression for the maximum variation:

$$dX_a\,(\max) = \frac{i}{\delta_{aa}\,\delta_{bb} - \delta^2_{ab}}\int \left|\,\delta_{bb}\left(\frac{M_o\, m_a}{E\,I} + X_a\,\frac{m^2_a}{E\,I} + X_b\,\frac{m_a\, m_b}{E\,I}\right)\right.$$
$$\left. - \,\delta_{ab}\left(\frac{M_o\, m_b}{E\,I} + X_a\,\frac{m_a\, m_b}{E\,I} + X_b\,\frac{m^2_b}{E\,I}\right)\right| ds \ldots\ldots\ldots\ldots (21)$$

MAXIMUM VARIATION OF STRESS QUANTITIES DEPENDENT ON STATIC UNKNOWNS

The greatest variations of stress quantities other than those chosen as static unknowns may be determined by two methods. In the first method different quantities are selected as static unknowns, including the stress quantities whose maximum variations are required, and then the problem is solved in the usual manner by the formulas presented herein.

In the second method, which is applicable only in cases when the variations of the original static unknowns have already been found for the same load condition, the variation of the new stress quantity is determined easily by differentiating the corresponding equation of statics. This may be best illustrated in an example.

Fig. 1 represents a fixed-ended rigid frame loaded on the horizontal part with a uniform load of intensity w. The structure is three times statically indeterminate. The bending moments at points A, B, and C, designated by X_a, X_b, and X_c, respectively, have been chosen as the unknowns, and their variations have been determined by Eq. 15. It is required to determine the greatest variation in M_E, the bending moment at the point E, the center of the horizontal part. By statics:

$$M_E = \frac{X_b + X_c}{2} + \frac{w L^2}{8} \qquad (22)$$

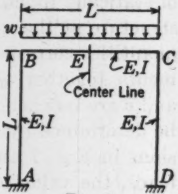

FIG. 1

Differentiating Eq. 22 and remembering that w and L are constant,

$$dM_E = \tfrac{1}{2}(dX_b + dX_c) \qquad (23a)$$

The three differentials in Eq. 23a may be considered as variations of the corresponding stress quantities. Since variations dX_b and dX_c are interdependent, it is incorrect to assign to them simultaneously the greatest values determined by Eq. 15. On the other hand, attributing to them the general integral expressions by Eq. 14 (in which the signs of the variations dE or dI in the variable terms i' at different points of the structure have not yet been specified) is quite legitimate. As a result of this substitution the following expression is obtained for the required greatest variation in M_E:

$$dM_E\ (\text{max}) = \frac{i}{D}\int \left| \tfrac{1}{2}\,[^b] + \tfrac{1}{2}\,[^c] \right| ds \qquad (23b)$$

in which the symbols $[^b]$ and $[^c]$ represent the brackets following the integral signs in the expressions for dX_b and dX_c.

MAXIMUM VARIATIONS FOR DIFFERENT LOAD CONDITIONS

Calculation of the maximum variation of a statically unknown quantity for a new load condition requires considerably less labor than a similar calculation for the first load, since the values of δ with subscripts a, b, and c, and the values of the determinants, are the same as in the first calculation. The quantities δ_{ao}, δ_{bo}, δ_{co} and the values of static unknowns X_a, X_b, and X_c are different, however.

The greatest variation dX_a, corresponding to two sets of loads acting simultaneously, may be found by superposing the results caused by separate actions of the two sets. However, it is not the numerical values of dX_a (max) that are to be superimposed but the expressions within the brackets in Eq. 15. The proof of this proposition may be derived by close inspection of the foregoing formulas. First, it should be realized that the expressions for the values of the moments M_o in the basic statically determinate structure, when both sets of loading are acting, may be obtained by superposition or algebraic addition of the values corresponding to separate sets. With this fact in mind it is easy to see that the quantities δ_{ao}, δ_{bo}, and δ_{co} (see Eq. 5*a*) also may be found by superposition, as concerns both the algebraic expressions under the integral signs and the numerical values obtained after the integration of these expressions. It is a well-known fact, evident also from Eq. 2, that the values of statically indeterminate quantities when two sets of loads are acting on the structure at the same time are equal to algebraic sums of the values of these quantities corresponding to separate actions of the loads. The last two statements, together with the fact that all δ and $d\delta$ quantities with subscripts a, b, and c are independent of the loads, make clear that Δ and $d\Delta$ values may also be determined by superposition, as may be seen from the form of their expressions in Eqs. 7 and 8. Since various determinants are also the same for all loads, the value of dX_a in Eq. 10 may likewise be found by superposition or (which is the same) the expression within the brackets of Eq. 14 for the two sets of loads presents an algebraic sum of the corresponding bracket expressions for the separate loads, which proves the required proposition.

However, the numerical value of dX_a (max) for the two sets of loads is different from the sum of numerical values corresponding to separate loads, because the zero points of the functions under the integral signs in the three cases concerned are generally different.

TWO-LEGGED FRAME OF CONSTANT MOMENT OF INERTIA

The fixed-ended frame shown in Fig. 1, with the height equal to the span and possessing constant moment of inertia, will be investigated for the greatest possible variations in the bending moments at the top end of one of the columns B and at the center of the beam part E, caused by variation in the value of the modulus of elasticity.

By introducing three hinges at points A, B, and C (Fig. 2(*a*)), the structure is made statically determinate and the corresponding determinate bending moments M_o are as shown. An unsymmetrical choice of static unknowns X_a, X_b, and X_c, representing the bending moments at the points A, B, and C, respectively, complicates the analysis but provides a means for checking the results, since the expressions for similar quantities at the points B and C will be obtained from equations in a dissimilar manner.

Moments m_a, m_b, and m_c, created in the statically determinate structure by unit moments acting at points A, B, and C, respectively, are shown in Figs. 2(*b*), 2(*c*), and 2(*d*). The sign convention for these moments, as well as for the static unknowns X_a, X_b, and X_c, is such that positive moments produce tension on the inside of the frame.

The δ-quantities are now expressed in the integral form and then evaluated. Both kinds of expression will be necessary in further calculation. The integral expressions of δ are composed of three parts, one for each leg of the frame and one for the beam part. In several δ-values, however, some of these integrals vanish because some of the moments M_o, m_a, m_b, or m_c are zero. Thus,

$$\left.\begin{array}{lllll}
\delta_{ao} = \int \frac{M_o\, m_a}{E\,I}\,ds = 0 & & & & \\
 & \overbrace{\hphantom{\int_0^L \frac{L}{E\,I}\left(1 - \frac{2\,y}{L}\right)}}^{\text{left leg}} & \overbrace{\hphantom{\int_0^L \frac{L}{E\,I}\left(1 - \frac{2\,x}{L}\right)}}^{\text{beam}} & \overbrace{\hphantom{\int_0^L \frac{L}{E\,I}\left(1 - \frac{2\,y}{L}\right)}}^{\text{right leg}} & \\
\delta_{bo} = \int \frac{M_o\, m_b}{E\,I}\,ds = & 0 & + \int_0^L \frac{w\,L^3}{2\,E\,I}\left(\frac{x}{L} - \frac{2\,x^2}{L^2} + \frac{x^3}{L^3}\right) d\left(\frac{x}{L}\right) + & 0 & = \frac{wL^3}{24\,E\,I} \\
\delta_{co} = & 0 & + \int_0^L \frac{w\,L^3}{2\,E\,I}\left(\frac{x^2}{L^2} - \frac{x^3}{L^3}\right) d\left(\frac{x}{L}\right) \quad + & 0 & = \frac{w\,L^3}{24\,E\,I} \\
\delta_{aa} = \int \frac{m_a\, m_a}{E\,I}\,ds = & \int_0^L \frac{L}{E\,I}\left(1 - \frac{2\,y}{L} + \frac{y^2}{L^2}\right) d\left(\frac{y}{L}\right) + & 0 & + \int_0^L \frac{L}{E\,I}\left(1 - \frac{2\,y}{L} + \frac{y^2}{L^2}\right) d\left(\frac{y}{L}\right) & = \frac{2\,L}{3\,E\,I} \\
\delta_{ab} = & \int_0^L \frac{L}{E\,I}\left(\frac{y}{L} - \frac{y^2}{L^2}\right) d\left(\frac{y}{L}\right) \quad + & 0 & - \int_0^L \frac{L}{E\,I}\left(1 - \frac{2\,y}{L} + \frac{y^2}{L^2}\right) d\left(\frac{y}{L}\right) & = -\frac{L}{6\,E\,I} \\
\delta_{ac} = & 0 \quad + & 0 & + \int_0^L \frac{L}{E\,I}\left(1 - \frac{y}{L}\right) d\left(\frac{y}{L}\right) & = \frac{L}{2\,E\,I} \\
\delta_{bb} = & \int_0^L \frac{L}{E\,I}\frac{y^2}{L^2}\, d\left(\frac{y}{L}\right) & + \int_0^L \frac{L}{E\,I}\left(1 - \frac{2\,x}{L} + \frac{x^2}{L^2}\right) d\left(\frac{x}{L}\right) & + \int_0^L \frac{L}{E\,I}\left(1 - \frac{2\,y}{L} + \frac{y^2}{L^2}\right) d\left(\frac{y}{L}\right) & = \frac{L}{E\,I} \\
\delta_{bc} = & 0 & + \int_0^L \frac{L}{E\,I}\left(\frac{x}{L} - \frac{x^2}{L^2}\right) d\left(\frac{x}{L}\right) & + \int_0^L \frac{L}{E\,I}\left(-1 + \frac{y}{L}\right) d\left(\frac{y}{L}\right) & = -\frac{L}{3\,E\,I} \\
\delta_{cc} = & 0 & + \int_0^L \frac{L}{E\,I}\left(\frac{x^2}{L^2}\right) d\left(\frac{x}{L}\right) & + \int_0^L \frac{L}{E\,I}\, d\left(\frac{y}{L}\right) & = \frac{4\,L}{3\,E\,I}
\end{array}\right\} \quad (24)$$

(c) MOMENTS m_b (d) MOMENTS m_c

FIG. 2.—MOMENT DIAGRAMS; SYMMETRICAL BENT, WITH CONSTANT MOMENT OF INERTIA

Having thus found all δ-values, it is now possible to set up the equations to determine the static unknowns and to compute the determinants required for the evaluation of dX_b (max). Eqs. 1 apply to this case as follows:

$$\left.\begin{aligned} \frac{2\,L}{3\,E\,I}X_a - \frac{L}{6\,E\,I}X_b + \frac{L}{2\,E\,I}X_c &= 0 \\ -\frac{L}{6\,E\,I}X_a + \frac{L}{E\,I}X_b - \frac{L}{3\,E\,I}X_c + \frac{w\,L^3}{24\,E\,I} &= 0 \\ \frac{L}{2\,E\,I}X_a - \frac{L}{3\,E\,I}X_b + \frac{4\,L}{3\,E\,I}X_c + \frac{w\,L^3}{24\,E\,I} &= 0 \end{aligned}\right\} \quad \text{.........}(25)$$

The value of the minor determinant corresponding to X_b in the first equation is

$$D_{1b} = \left(-\frac{L}{3\,E\,I}\right)\left(\frac{L}{2\,E\,I}\right) - \left(-\frac{L}{6\,E\,I}\right)\left(\frac{4\,L}{3\,E\,I}\right) = \frac{1}{18}\left(\frac{L}{E\,I}\right)^2 \text{..}(26a)$$

Similarly,

$$D_{2b} = \frac{23}{36}\left(\frac{L}{E\,I}\right)^2 \quad \text{and} \quad D_{3b} = \frac{5}{36}\left(\frac{L}{E\,I}\right)^2 \text{.........}(26b)$$

The major determinant, made up of all the coefficients of the unknowns, is found to be

$$D = \frac{7}{12}\left(\frac{L}{E\,I}\right)^3 \text{.......................}(26c)$$

On solving the equations the values of the static unknowns come out:

$$\left.\begin{aligned} X_a &= \frac{1}{36}\,w\,L^2 \\ X_b &= -\frac{1}{18}\,w\,L^2 \\ X_c &= -\frac{1}{18}\,w\,L^2 \end{aligned}\right\}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(27)$$

the two latter values being equal as might be expected from symmetry.

The next step is to set up the integral expressions for the three functions Δ by Eq. 7:

$$\begin{aligned} \Delta_a = {} & \frac{w\,L^3}{36}\Bigg[\overbrace{\int_0^L \frac{1}{E\,I}\left(1-\frac{2\,y}{L}+\frac{y^2}{L^2}\right)d\left(\frac{y}{L}\right)}^{\text{left leg}} \overset{\text{beam}}{+0+} \overbrace{\int_0^L \frac{1}{E\,I}\left(1-\frac{2\,y}{L}+\frac{y^2}{L^2}\right)d\left(\frac{y}{L}\right)}^{\text{right leg}}\Bigg] \\ & -\frac{w\,L^3}{18}\Bigg[\int_0^L \frac{1}{E\,I}\left(\frac{y}{L}-\frac{y^2}{L^2}\right)d\left(\frac{y}{L}\right) +0- \int_0^L \frac{1}{E\,I}\left(1-\frac{2\,y}{L}+\frac{y^2}{L^2}\right)d\left(\frac{y}{L}\right)\Bigg] \\ & -\frac{w\,L^3}{18}\Bigg[\qquad 0 \qquad +0+ \int_0^L \frac{1}{E\,I}\left(1-\frac{y}{L}\right)d\left(\frac{y}{L}\right)\Bigg] \\ & + \qquad 0 \qquad +0+ \qquad 0 \\ = {} & \frac{w\,L^3}{36}\Bigg[\int_0^L \frac{1}{E\,I}\left(1-\frac{4\,y}{L}+\frac{3\,y^2}{L^2}\right)d\left(\frac{y}{L}\right)+0+\int_0^L \frac{1}{E\,I}\left(1-\frac{4\,y}{L}+\frac{3\,y^2}{L^2}\right)d\left(\frac{y}{L}\right)\Bigg] \quad (28) \end{aligned}$$

Within all brackets in Eq. 28 the first integrals refer to the left leg of the frame, the second (which in case of Δ_a are zero) to the beam part, and the third to the right leg. In arriving at the final expression for Δ_a it is the integrals referring to the same part of the frame that are combined, whereas the integrals referring to different parts remain separate. Similarly:

$$\left.\begin{aligned} \Delta_b = {} & \frac{w\,L^3}{36}\Bigg[\overbrace{\int_0^L \frac{1}{E\,I}\left(\frac{y}{L}-\frac{3\,y^2}{L^2}\right)d\left(\frac{y}{L}\right)}^{\text{left leg}} - \overbrace{\int_0^L \frac{1}{E\,I}\left(2-\frac{20\,x}{L}+\frac{36\,x^2}{L^2}-\frac{18\,x^3}{L^3}\right)d\left(\frac{x}{L}\right)}^{\text{beam}} \\ & \qquad - \overbrace{\int_0^L \frac{1}{E\,I}\left(1-\frac{4\,y}{L}+\frac{3\,y^2}{L^2}\right)d\left(\frac{y}{L}\right)}^{\text{right leg}}\Bigg] \\ \Delta_c = {} & \frac{w\,L^3}{36}\Bigg[\overbrace{\qquad\qquad 0 \qquad\qquad}^{\text{left leg}} - \overbrace{\int_0^L \frac{1}{E\,I}\left(\frac{2\,x}{L}-\frac{18\,x^2}{L^2}+\frac{18\,x^3}{L^3}\right)d\left(\frac{x}{L}\right)}^{\text{beam}} \\ & \qquad - \overbrace{\int_0^L \frac{1}{E\,I}\left(-1+\frac{3\,y}{L}\right)d\left(\frac{y}{L}\right)}^{\text{right leg}}\Bigg] \end{aligned}\right\}(29)$$

These expressions for various values of Δ have been checked by evaluating the integrals on the assumption that $E\,I$ is constant and by finding that all Δ's then vanish.

Moment X_b.—The expression for the greatest possible variation of X_b is found by multiplying the integral expressions of various Δ's by their minor determinants, in accordance with Eq. 15, and by recombining the integrals:

$$dX_b\,(\max) = \frac{i}{\frac{7}{12}\left(\frac{L}{E\,I}\right)^3}\left(\frac{L}{E\,I}\right)^2 \frac{w\,L^3}{36\,E\,I}$$

$$\times\Bigg[\overbrace{\int_0^L \Bigg|\frac{1}{18}\left(1-\frac{4\,y}{L}+\frac{3\,y^2}{L^2}\right)+\frac{23}{36}\left(\frac{y}{L}-\frac{3\,y^2}{L^2}\right)+\frac{5}{36}(0)\Bigg|}^{\text{left leg}}$$

$$\overbrace{+\int_0^L \Bigg|\frac{1}{18}(0)+\frac{23}{36}\left(-2+\frac{20\,x}{L}-\frac{36\,x^2}{L^2}+\frac{18\,x^3}{L^3}\right)+\frac{5}{36}\left(-\frac{2\,x}{L}+\frac{18\,x^2}{L^2}-\frac{18\,x^3}{L^3}\right)\Bigg|\,d\left(\frac{x}{L}\right)}^{\text{beam}}$$

$$\overbrace{+\int_0^L \Bigg|\frac{1}{18}\left(1-\frac{4\,y}{L}+\frac{3\,y^2}{L^2}\right)+\frac{23}{36}\left(-1+\frac{4\,y}{L}-\frac{3\,y^2}{L^2}\right)+\frac{5}{36}\left(1-\frac{3\,y}{L}\right)\Bigg|\,d\left(\frac{y}{L}\right)}^{\text{right leg}}\Bigg]$$

$$=\frac{w\,L^2}{756}\,i\,\Bigg[\overbrace{\int_0^L \Bigg|2+\frac{15\,y}{L}-\frac{63\,y^2}{L^2}\Bigg|\,d\left(\frac{y}{L}\right)}^{\text{left leg}}$$

$$\overbrace{+2\int_0^L \Bigg|-23+\frac{225\,x}{L}-\frac{369\,x^2}{L^2}+\frac{162\,x^3}{L^3}\Bigg|\,d\left(\frac{x}{L}\right)}^{\text{beam}}$$

$$\overbrace{+\int_0^L \Bigg|-16+\frac{69\,y}{L}-\frac{63\,y^2}{L^2}\Bigg|\,d\left(\frac{y}{L}\right)}^{\text{right leg}}\Bigg] \quad \ldots\ldots\ldots\ldots\ldots (30a)$$

In Eq. 30*a* each integration must be performed with respect to the numerical values of the functions under the integral signs, rather than with respect to the functions themselves, as is indicated by the sign $|\,|$. This necessitates the determination of the points at which the expressions under the integral signs become zero.

Left Leg.—On solving the quadratic it is found that the function under the integral sign becomes zero at the points $y = \frac{1}{3}\,L$ and $y = -\frac{2}{21}\,L$, of which the latter value is outside of the range considered. Therefore:

$$\int_0^L \left|2 + \frac{15\,y}{L} - \frac{63\,y^2}{L^2}\right| d\left(\frac{y}{L}\right) = \left|\int_0^{L/3} \left(2 + \frac{15\,y}{L} - \frac{63\,y^2}{L^2}\right) d\left(\frac{y}{L}\right)\right|$$

$$+ \left|\int_{L/3}^L \left(2 + \frac{15\,y}{L} - \frac{63\,y^2}{L^2}\right) d\left(\frac{y}{L}\right)\right| = \left|\frac{13}{18}\right| + \left|-\frac{220}{18}\right| = \frac{233}{18} = 12.944.$$

Beam Part.—An approximate solution of the cubic equation in x gives the following values: $x = 0.128\,L$ and $x = 0.874\,L$. Integrating separately in the three intervals between the limits 0, $0.128\,L$, $0.874\,L$, and L, and adding the numerical values of the results:

$$\int_0^L \left|-23 + \frac{225\,x}{L} - \frac{369\,x^2}{L^2} + \frac{162\,x^3}{L^3}\right| d\left(\frac{x}{L}\right)$$

$$= |-1.347| + |8.624| + |-0.272| = 10.243.$$

Right Leg.—The integration must be performed separately between the limits $0, \frac{1}{3}\,L, \frac{16}{21}\,L$, and L:

$$\int_0^L \left|-16 + \frac{69\,y}{L} - \frac{63\,y^2}{L^2}\right| d\left(\frac{y}{L}\right) = \left|-\frac{41}{18}\right| + \left|\frac{81}{98}\right| + \left|-\frac{925}{882}\right| = 4.153.$$

Summation.—Substituting these numerical values of the integrals in the expression for the required variation (Eq. 30*a*):

$$dX_b\,(\max) = \frac{w\,L^2}{756}\,i\,[12.944 + 2(10.243) + 4.153]$$

$$= 0.0497\,i\,w\,L^2 = 0.894\,i\,|X_b|\ \ (30b)$$

in which $X_b = -\frac{1}{18}\,w\,L^2$, as has been found, and 0.894 is the value of the coefficient K expressed by Eq. 16.

Parts of the frame over which the modulus of elasticity must be increased or decreased in order to cause the greatest possible variation in the numerical value of the bending moment X_b are shown in Fig. 3, the stiffened parts being indicated by heavy lines, and the ones that are made less stiff—by light lines.

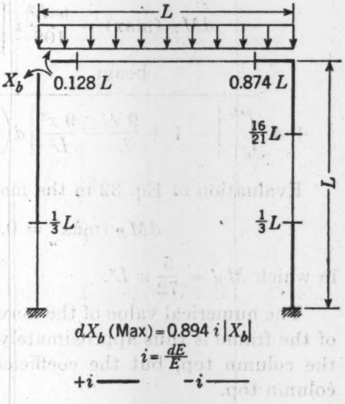

FIG. 3

Moment X_c.—A similar procedure leads to the following expression for the greatest variation in the value of the moment X_c at the top of the right column:

$$\begin{aligned} dX_c\,(\text{max}) = \frac{w\,L^2}{756}\, i \Bigg[& \overbrace{\int_0^L \left| -16 + \frac{69\,y}{L} - \frac{63\,y^2}{L^2} \right| d\left(\frac{y}{L}\right)}^{\text{left leg}} \\ & + \overbrace{2 \int_0^L \left| -5 + \frac{27\,x}{L} + \frac{117\,x^2}{L^2} - \frac{162\,x^3}{L^3} \right| d\left(\frac{x}{L}\right)}^{\text{beam}} \\ & + \overbrace{\int_0^L \left| 2 + \frac{15\,y}{L} - \frac{63\,y^2}{L^2} \right| d\left(\frac{y}{L}\right)}^{\text{right leg}} \Bigg] \quad \ldots\ldots\ldots\ldots\ldots (31) \end{aligned}$$

Comparing Eq. 31 with Eq. 30*a*, it may be noticed that the first and the third integrals in the former are identical with the third and the first integrals, respectively, in the latter. Furthermore, replacement of the variable x by $(L - x)$ in the second integral of Eq. 31 leads to an expression identical with the second integral in Eq. 30*a*. These relationships between the expressions for dX_b (max) and dX_c (max), of course, are the direct result of the symmetry of points B and C on the symmetrical frame, and they lead to an equality of the numerical values of the variations considered.

Bending Moment at the Center of the Frame.—The greatest variation of the bending moment at the center of the frame E is found by Eq. 23*b*:

$$\begin{aligned} dM_E\,(\text{max}) = \frac{w\,L^2}{108}\, i \Bigg[& \overbrace{\int_0^L \left| -1 + \frac{6\,y}{L} - \frac{9\,y^2}{L^2} \right| d\left(\frac{y}{L}\right)}^{\text{left leg}} \\ & + \overbrace{4 \int_0^L \left| -1 + \frac{9\,x}{L} - \frac{9\,x^2}{L^2} \right| d\left(\frac{x}{L}\right)}^{\text{beam}} + \overbrace{\int_0^L \left| -1 + \frac{6\,y}{L} - \frac{9\,y^2}{L^2} \right| d\left(\frac{y}{L}\right)}^{\text{right leg}} \Bigg] \quad . (32) \end{aligned}$$

Evaluation of Eq. 32 in the manner illustrated previously leads to:

$$dM_E\,(\text{max}) = 0.0460\, i\, w\, L^2 = 0.663\, i\, M_E \ldots\ldots\ldots\ldots (33a)$$

in which $M_E = \dfrac{5}{72}\, w\, L^2$.

The numerical value of the maximum variation of the moment at the center of the frame is thus approximately equal to the value of a similar quantity at the column top, but the coefficient K at the center is smaller than at the column top.

It has also been found that

$$dX_a\,(\text{max}) = 0.0447\, i\, w\, L^2 = 1.609\, i\, X_a \ldots\ldots\ldots\ldots (33b)$$

in which $X_a = \dfrac{w\,L^2}{36}$.

The greatest variation in the moment M_E in the same structure has been determined also for a different load condition—namely, for a vertical concentrated load P acting at the center of the frame. New loading creates new values of δ_{ao}, δ_{bo}, δ_{co} and of the static unknowns. The other δ's and the determinants remain the same. The results are as follows:

$$X_a = \frac{1}{24} P\,L; \qquad X_b = X_c = -\frac{1}{12} P\,L; \qquad M_E = \frac{P\,L}{6};$$

and

$$\begin{aligned} dM_E\,(\max) = \frac{P\,L}{72} i \Bigg[& \overbrace{\int_0^L \left| -1 + \frac{6\,y}{L} - \frac{9\,y^2}{L^2} \right| d\left(\frac{y}{L}\right)}^{\text{left leg}} \\ & + \overbrace{\int_0^{L/2} \left| -4 + \frac{24\,x}{L} \right| d\left(\frac{x}{L}\right)}^{\text{beam, left half}} + \overbrace{\int_{L/2}^{L} \left| 20 - \frac{24\,x}{L} \right| d\left(\frac{x}{L}\right)}^{\text{beam, right half}} \\ & + \overbrace{\int_0^L \left| -1 + \frac{6\,y}{L} - \frac{9\,y^2}{L^2} \right| d\left(\frac{y}{L}\right)}^{\text{right leg}} \Bigg] = 0.074\, i\,P\,L = 0.4444\, i\,M_E \quad (34a) \end{aligned}$$

The greatest variation in M_E in the structure loaded with both the uniform and the concentrated loads of the previous problems can be found by direct superposition of the corresponding integral expressions. Assuming, for example, that $P = w\,L$, the following expression is developed for dM_E (max):

$$\begin{aligned} dM_E\,(\max) = \frac{P\,L}{216} i \Bigg[& 5 \overbrace{\int_0^L \left| -1 + \frac{6\,y}{L} - \frac{9\,y^2}{L^2} \right| d\left(\frac{y}{L}\right)}^{\text{left leg}} \\ & + \overbrace{4 \int_0^{L/2} \left| -5 + \frac{36\,x}{L} - \frac{18\,x^2}{L^2} \right| d\left(\frac{x}{L}\right)}^{\text{beam, left half}} + \overbrace{4 \int_{L/2}^{L} \left| 13 - \frac{18\,x^2}{L^2} \right| d\left(\frac{x}{L}\right)}^{\text{beam, right half}} \\ & + \overbrace{5 \int_0^L \left| -1 + \frac{6\,y}{L} - \frac{9\,y^2}{L^2} \right| d\left(\frac{y}{L}\right)}^{\text{right leg}} \Bigg] = 0.1196\, i\,P\,L = 0.5067\, i\,M_E \quad (34b) \end{aligned}$$

in which $M_E = \frac{17}{72} P\,L$.

Two-Hinged Frame of Variable Moment of Inertia

In problems discussed thus far, expressions following the integral signs have been such that the integrations could be performed easily. In more complicated cases integrations must be replaced by summations.

In the uniformly loaded frame shown in Fig. 4 the thickness of the legs changes linearly from 24 in. at the hinge to 36 in. at the top. The thickness of the horizontal member varies from 16 in. at the center to 36 in. at the ends, following the law of a semicubic parabola:

$$h = \frac{4}{3}\,(1 + 0.01\,x^{3/2}) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

in which both h and x are expressed in feet. The structure is typical for rigid-frame reinforced-concrete bridges except for the somewhat impractical rectangular outline of the axis. However, this peculiarity of the form, assumed for simplicity of calculation, affects the structural behavior of the frame only slightly. It is required to find the greatest variations of thrust and bending moments at different points of the structure due to variation of the modulus of elasticity. The horizontal thrust H, assumed to act outwardly on the structure, is the only static unknown. If horizontal restraint is removed, the bending moment in the horizontal part of the frame becomes $M_o = \frac{w}{2}\,(25^2 - x^2)$, and no flexure occurs in the legs. When unit outward thrusts act on the structure, the moments m_a assume the values shown in Fig. 5. The frame is 1 ft wide. Expressions for δ's after simplification are as follows:

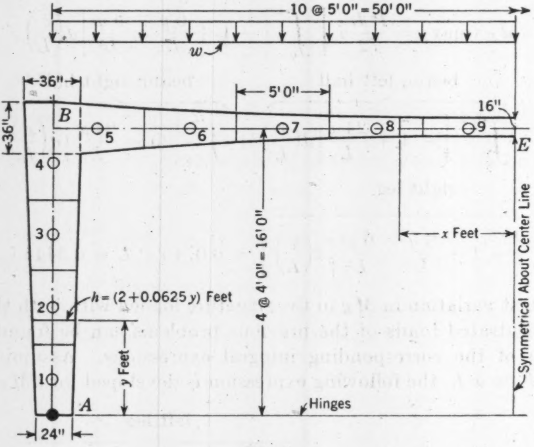

FIG. 4

$$\left.\begin{aligned} \delta_{ao} &= \overset{\text{left leg}}{0} + \overbrace{81\,w\int_0^{25}\frac{(25^2 - x^2)\,dx}{(1 + 0.01\,x^{3/2})^3\,E}}^{\text{beam}} + \overset{\text{right leg}}{0} \\ \delta_{aa} &= \overbrace{2(12)^4\int_0^{16}\frac{y^2\,dy}{(24 + 0.75\,y)^3\,E}}^{\text{two legs}} + \overbrace{2(6)^4\int_0^{25}\frac{dx}{(1 + 0.01\,x^{3/2})^3\,E}}^{\text{beam}} \end{aligned}\right\} \ldots (36)$$

For the purpose of summation, the structure is divided into eighteen sections 4 ft and 5 ft long, as shown in Fig. 4. The sectional increments of δ_{ao} and δ_{aa} (that is, the values of the expressions under the integral signs of all sections multiplied by their respective values of dx or dy) are given in Table 1, together with the values of δ_{ao} and δ_{aa} themselves. Then

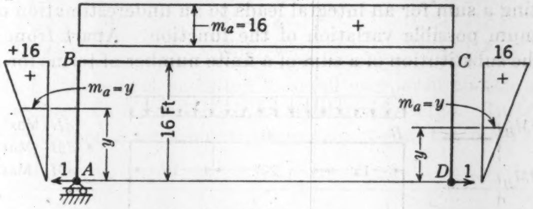

FIG. 5

$$H = -\frac{\delta_{ao}}{\delta_{aa}} = -15.54\,w \ldots\ldots\ldots\ldots\ldots\ldots (37a)$$

The greatest variation in H may be found by Eq. 20b, which for finite summation becomes:

$$dH\ (\text{max}) = \frac{i}{\delta_{aa}} \sum |\text{Increment of } [\,\delta_{ao} + H\,\delta_{aa}\,]| \ldots\ldots\ldots (37b)$$

The values of increments of the expression in brackets are stated in Table 1. All data in this table, as well as the foregoing formulas for δ_{ao}, δ_{aa}, and other values, are given in feet units, and the values in the table refer to the sums of corresponding increments for the pairs of sections located symmetrically with respect to the vertical axis, so that the summation need be extended only over one half of the structure.

Substituting the numerical values from Table 1, the greatest variation of the thrust proves to be:

$$dH\ (\text{max}) = 4.18\,w\,i$$
$$= 0.269\,i\,|H| \ldots\ldots (37c)$$

In this equation w is expressed in feet units, and so are the various stress quantities to the end of this chapter.

The variations of the moments at the knee and at the crown are found by differentiating the equations of statics relating these moments with H. Calling moment at the knee M_B and at the crown M_E:

$$dM_B\ (\text{max}) = dM_E\ (\text{max}) = 16\,dH\ (\text{max}) = 66.91\,w\,i \ldots\ldots (37d)$$

Since $M_B = -248.65\,w$ and $M_E = 63.85\,w$, dM_E (max) $= 1.048\,i\,M_E$ and dM_B (max) $= 0.269\,i\,|M_B|$. Fig. 6 shows the parts of the frame that are modified in stiffness for the purpose of creating the greatest variations in H, M_B, and M_E.

Susbtituting a sum for an integral leads to an underestimation of the value of the maximum possible variation of the function. Apart from some error inherent in the substitution of a sum of a finite number of terms for an integral, the value of the greatest possible variation of a function may be substantially the same for integration and summation only if all the zero points of the expression under the integral sign coincide with the boundaries of sections. Since such a condition is not likely to occur, the increment of the sum for the section containing a zero point will be approximately equal to an algebraic sum of the positive and negative areas under the curve in this particular section instead of the sum of the numerical values of the two areas. That means that the value found by summation should be somewhat less than the one found by integration. The difference of the two values, however, is not likely to be great.

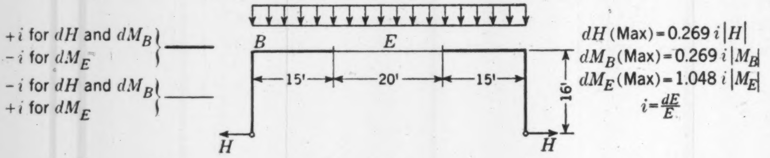

FIG. 6

The uniformly loaded rigid frame of Fig. 4 also has been analyzed, assuming the bottom ends of the columns as fixed. Thus modified, the structure becomes three times statically indeterminate. The following results have been obtained, using feet units: $H = -22.04\,w$; $M_A = 100.00\,w$; $M_B = -252.58\,w$; $M_E = 59.92\,w$; dH (max) $= 0.421\,i\,|H|$; dM_A (max) $= 1.567\,i\,M_A$; dM_B (max) $= 0.496\,i\,|M_B|$; and dM_E (max) $= 1.047\,i\,M_E$.

Comparing the fixed-ended frame with the two-hinged frame, it may be seen that dH (max) and dM_B (max) increase considerably when column supports become fixed—increase both in absolute values and in relation to the magnitudes of H and M_B themselves. On the other hand, dM_E (max) remains practically the same.

TWO-HINGED TRUSSED ARCH

As an example of a trussed structure, the two-hinged arch of Fig. 7, uniformly loaded, has been investigated for the maximum possible variations of the thrust and of the stresses in some of the members, caused by variation in E. The cross-sectional areas of all members have been assumed equal. The only static unknown, the thrust, and its greatest variation have been found to be: $H = -135.36\,w$; and dH (max) $= 0.187\,i\,|H|$, with w in feet units.

The greatest variations of stresses in the truss members have been found by differentiating the expressions for these stresses stated in terms of H. Some of the stresses and their variations are:

Member (Fig. 7)	Stress S	Maximum variation
$L_0 L_1$	$-166.77\ w$	$0.187\ i\lvert S\rvert$
$U_4 U_5$	$-103.9\ w$	$1.22\ i\lvert S\rvert$
$U_3 L_4$	$38.6\ w$	$1.21\ i\lvert S\rvert$

In member $L_0 L_1$ the stress variation is small compared to the stress itself, whereas in members $U_4 U_5$ and $U_3 L_4$ it is relatively large. In the first two members, uniform load over the entire span represents the most unfavorable condition of loading, and the same is approximately true for the third member considered. In several other members maximum stress variations prove to be even larger in proportion to their respective stresses than in the foregoing three members, but their stresses themselves are relatively small, since the loading considered is by far not the most unfavorable one.

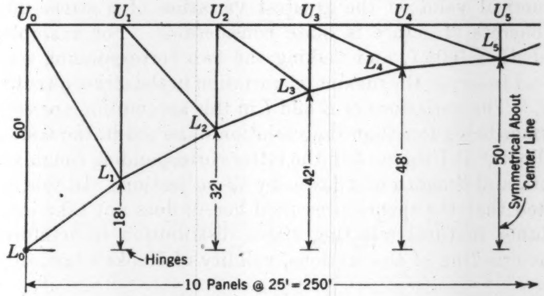

FIG. 7

CONCLUSION

It must be realized clearly that the variation of the static unknown discussed in this paper is an extreme quantity that may be attained only in an exceptional case when the variations of the elastic characteristics causing it assume their maximum possible values (positive or negative), arranged with regard to signs in the most unfavorable and unique manner along the structure. In spite of its improbability, the variation herein considered has a genuine significance as a limiting quantity that the actual deviations of stress functions from their theoretical values cannot exceed, but may approach, in unfavorable cases.

Furthermore, the maximum variation of a stress quantity may be viewed as a measure of the sensitivity of this quantity to small unforeseen and accidental changes in elastic characteristics. Coefficient K in Eq. 16 can be called the coefficient of sensitivity. The higher its value, the more sensitive is the stress quantity to small variations in E, I, or A. Thus, the moment at the crown of the frame of Fig. 4 is much more sensitive to variation in E than the moment at the knee.

From the examples solved it may be seen that the K-values frequently equal unity and occasionally are as high as 1.5 or even 2.0. On the other hand, they are often as low as 0.15 to 0.20. It is possible that there is general increase in sensitivity as the number of static unknowns increases. At least, a comparison of the results for two-hinged and fixed-ended frames suggests this possibility; but the evidence supporting this statement is inconclusive.

In theory, the coefficient of relative variation of the elastic characteristic i is an infinitesimal quantity, but in actual computation it must be given an appropriate finite value, disregarding the error that may result from such assumption.

The numerical value of the greatest variation of a stress quantity in a reinforced-concrete structure is quite considerable. For example, using $dE = 0.2\,E$ and $dI = 0.04\,I$, and making the two corresponding sensitivity coefficients equal to unity, the maximum variation in the stress quantity X proves to be $0.24\,X$. The variations of E and I in this assumption are very conservative, the former being less than the variation observed in the tests at the University of Illinois,[2] at Urbana, and the latter corresponding roughly to a ± ⅛-in. error in depth and breadth of a 12-in. by 12-in. section. In this connection it may be stated that the theory presented herein does not take into consideration such other features affecting stress distribution in reinforced-concrete structures as cracking of the sections, validity of Hooke's law, shrinkage, and plastic flow.

In the tests at the University of Illinois some of the moments at column bases differed from theory much more than the 24% found in the foregoing example. The discrepancy, however, was attributed to cracking. In steel structures the greatest variations of stress quantities from the cause herein considered are not likely to be more than 3% to 5% of their values.

The foregoing suggests the futility of using involved methods for finding the "exact" values of stress quantities in most statically indeterminate, reinforced-concrete structures, and it encourages the use of approximate methods. On the other hand, in structures of great importance the determination of maximum values of stress quantities appears insufficient, and must be supplemented by a determination of the greatest variations of these functions.

It is reasonable also to conclude that the legitimate fluctuation of stress values discussed herein should be allowed for by varying working stresses in amounts depending on the sensitivity of the function in question, unless the member is designed on the basis of the theoretical value of the stress computed, modified by the amount of its maximum variation.

APPENDIX

NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials, prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:[3]

b = breadth of a structural member;
C = constants;
D = a determinant;
E = Young's modulus;
H = a horizontal thrust;
h = height or depth of cross section of a structural member;
I = moment of inertia;
i = a small, theoretically infinitesimal, quantity which is a measure of the greatest variation of an elastic characteristic: $i = \frac{dE}{E}, \frac{dI}{I}$, etc.
K = coefficient representing the maximum percentage by which values of X may change when elastic characteristics change by one per cent;
L = length or height of a structural member;
M = bending moment for structures consisting of flexural members:
  M_E = moment at point E, etc.;
  M_o = moment due to the externally applied loading;
m = moment due to a unit load for members subjected to flexure only:
  m_a = moment due to $X_a = 1$;
  m_b = moment due to $X_b = 1$;
N = direct stress for structures consisting of direct-stress members only;
n = direct stress due to a unit load, for structures consisting of direct-stress members only;
P = a concentrated load;
ds = a small element of a member;
w = a uniform load intensity;
X = a statically unknown force: X_a = force at point a, etc.;
ϵ = an elastic characteristic; and
δ = movement of the point of application of a static unknown in the direction of the unknown.

DISCUSSION

A. H. Finlay,[4] **Assoc. M. Am. Soc. C. E.**—Professor Hrennikoff has presented an intriguing paper with clarity and precision. Others[5] previously have determined the effect of variations of the elastic characteristics of structures upon the statically indeterminate stress functions, but these workers have confined themselves to arbitrary distributions of such variations throughout the structure. To the writer's knowledge, the author is the first to develop a method determining the maximum effect that a variation of specified magnitude may exert upon a given stress function. In so doing he defines the "pattern" to which such a variation must conform.

The author's applications of his method to several specific structures reveal that substantial variations in the stress functions are at least within the realms of possibility and the profession is fortunate to have the problem placed upon a quantitative basis.

In order to interpret the significance of the expressions under the integral signs in the author's various equations (such as Eq. 30*a*), the writer has plotted the functions concerned for a special case—a square frame having members of uniform cross section and carrying a uniform load on the horizontal member. In Fig. 8, curves have been plotted for those expressions associated with dX_a, dX_b, and dM_E, defined, respectively, as follows:

$$dX_a\,(\text{max}) = \frac{w\,L^2\,i}{378}\,A_a \qquad \text{(38}a\text{)}$$

$$dX_b\,(\text{max}) = \frac{w\,L^2\,i}{756}\,A_b \qquad \text{(38}b\text{)}$$

and

$$dM_E\,(\text{max}) = \frac{w\,L^2\,i}{108}\,A_E \qquad \text{(38}c\text{)}$$

in which A is the area under each respective curve, without regard to sign. (The graph of the function under the integral for dX_c is similar to Fig. 8(*b*), but "opposite hand.") These areas are, of course, measures of the maximum values that dX_a, dX_b, and dM_E may attain. It should be noted that the areas under these curves with regard to sign are zero since a uniform change in an elastic characteristic (that is, with constant i) produces no change in the statically indeterminate forces. It is the fact that i may be positive in those parts of the structure where such areas are positive, and negative in those parts where the areas are negative (or vice versa), that leads to the possibility of the substantial errors found by the author. It is also apparent from the curves that considerable errors may still occur in the stress functions even though chance fails to cause a change in the sign of i in strict accordance with the pattern.

[5] "Dependability of the Theory of Concrete Arches," by Hardy Cross, *Bulletin No. 203*, Univ. of Illinois Eng. Experiment Station, Urbana, Ill., 1930.

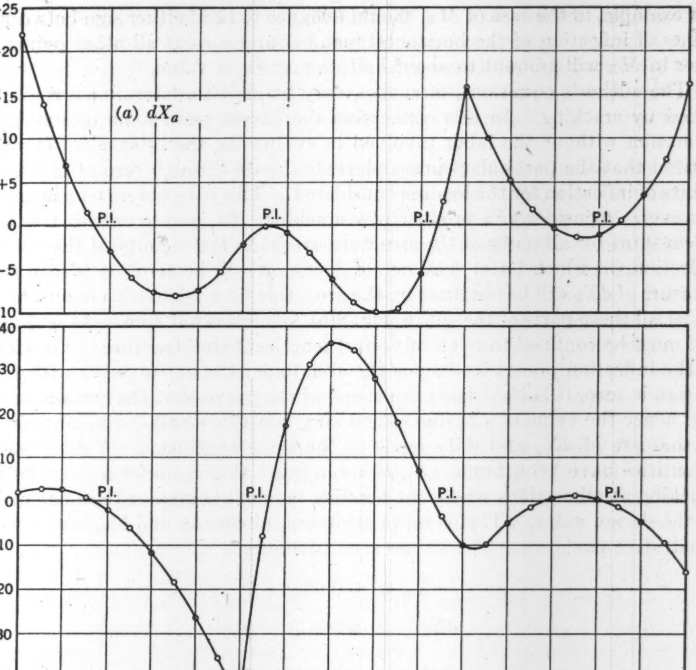

FIG. 8.—GRAPHS OF FUNCTIONS UNDER INTEGRAL SIGNS IN THE AUTHOR'S EQUATIONS (SUCH AS EQ. 30a)

For example, in the case of M_E, should i chance to be of either sign between the points of inflection of the horizontal member and zero at all other points, the error in M_E will amount to about half its maximum value.

The author's equations, of course, may be used to determine errors introduced by cracking. In this connection the curves yield some interesting information without the labor involved in evaluating the integrals. It will be noticed that the particular curves plotted all pass through zero at or near the points of inflection for the loading considered. This may not be true in general, however. Consider dX_b produced by cracking: If i, due to cracking, is taken as constant for all parts of the structure except in the vicinity of the points of inflection (in which latter sections, of course, it will be zero), it is seen that a measure of dX_b will be obtained by the area, this time taken with regard to sign, under all those parts of the curve, Fig. 8(*b*), where i is not zero. As zero values of i must be confined to relatively short lengths of the structure in the vicinity of the inflection points, and since the area under the entire curve with regard to sign is zero, it is clear from the shape of the curve that the remaining area, and hence the value of dX_b due to cracking, must be small. Similar reasoning in the case of dX_a and dM_E leads to the same conclusion. Values of these quantities have been found on the assumption that a uniform i results from cracking at all sections where the bending moment is greater than one quarter of the design value. This is quite arbitrary, of course, and has been used for illustrative purposes. The values are as follows:

$$dX_a = +\,0.0358\, i\, X_a \qquad (39a)$$

$$dX_b = -\,0.00573\, i\, |\, X_b\, | \qquad (39b)$$

and

$$dM_E = -\,0.00321\, i\, M_E \qquad (39c)$$

It should be noted that, in Eqs. 39, i carries a sign and, since cracking reduces the moment of inertia, i should be substituted in Eqs. 39 as a negative quantity. The errors are seen to be extremely small, as could have been anticipated from the curves.

Had i been assumed as a variable quantity, the curves in Fig. 8, of course, would have been different, since i could not have been left outside the integral sign. As an approximation, however, the curves as plotted could be used in such a case. The areas under various parts of them then would have to be multiplied by the value of i assumed to exist over the section in question. This, of course, is equivalent to assuming that i is constant along short sections of the structure but varies abruptly from section to section. It still seems clear, however, from the characteristics of the curves and the fact that i is everywhere of the same sign, that errors in the statically indeterminate forces due to cracking will be of a smaller order altogether than those which may arise due to chance variations in the elastic characteristics.

The writer is in complete agreement with the author's concluding paragraphs, and he also feels that the paper should prove of considerable interest to those whose lot it is to explain discrepancies between observed and calculated quantities in the field of rigid-frame testing.

Stefan J. Fraenkel,[6] **Jun. Am. Soc. C. E.**—In the writer's opinion, the method presented by Professor Hrennikoff constitutes a valuable contribution to structural analysis and is the first ever suggested along this particular line. The author is to be commended for having devised this thorough and workable solution of a problem otherwise rather beset with difficulties which often make an exact solution impracticable.

It is important to realize the limitations to which this method is subject, as far as its application to the field of design is concerned. Professor Hrennikoff rightly states that in steel structures the variation of stress quantities is very small. Even assuming that the variation amounts to 5%, the resulting additional stress would, in most structures, be smaller than stresses caused by secondary stresses, poorly maintained pin connections, etc. The main field of application, therefore, would lie in the realm of reinforced-concrete structures. Even there, enough uncertainties enter into a design to make unnecessary an investigation along the lines suggested in the paper, except in the very largest structures. It should be possible, however, to put this method to excellent use for purposes of investigation in the following manner:

During the construction of a reinforced-concrete structure, test cylinders of the material could be taken at regular intervals along the structure, and the values of E of these cylinders then could be determined. The maximum value of i, and, consequently, the maximum possible variation of any stress quantity may then be computed for the particular case. Further, the deviations of E and I from their average values within the intervals defined by the roots of Eq. 15 could be investigated, and their algebraic signs would furnish an indication of how closely the theoretical sensitivity coefficient would be approximated. Although this information undoubtedly would be of interest, it would constitute little more than a "post-mortem" examination, and its results would not be applicable to a future design.

A tabulation of sensitivity coefficients for different structures would be a helpful guide to designers, although more in a qualitative than in a quantitative way. Inasmuch as design is still to a considerable degree a matter of judgment, some indication thus would be available to the designer as to where to exercise particular caution. The recommendation that the working stresses be varied in amounts proportional to the sensitivity of the function in question, although theoretically sound, would seem to the writer to be, in effect, wasteful of materials. In framed indeterminate structures it is impossible in any case to stress all members to the allowable unit stress.

To satisfy his curiosity, the writer applied Professor Hrennikoff's method to an arch rib of uniform cross section and of uniform outline. In presenting the results of this investigation, the writer wishes to state that, unless summation is substituted for integration, it will be necessary, in the case of structures with curved center lines, to solve for the roots of algebraic polynomials of the fourth degree, or even higher, which is a tedious process. A computing machine is almost indispensable, inasmuch as the ordinates of the functions are obtained as differences of large numbers. The writer used the slide rule and had to make extensive long-hand computations in order to gain a tolerable accuracy.

---

[6] Care, Eng. Dept., Pittsburgh-Des Moines Steel Co., Neville Island, Pittsburgh, Pa.

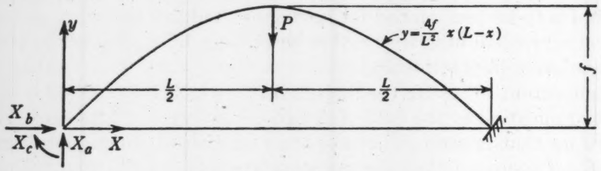

FIG. 9

The arch shown in Fig. 9 was loaded with a concentrated load P at the center, and its equation is

$$y = \frac{4\,f}{L^2}\,x\,(L - x) \qquad \text{(40)}$$

The statically indeterminate quantities are shown at the left abutment.

After a routine application of the Maxwell-Mohr method, the values of the unknowns were found to be as follows:

$$X_a = \tfrac{1}{2}\,P; \qquad X_b = \frac{15}{64}\,\frac{P\,L}{f}; \qquad \text{and} \qquad X_c = \frac{P\,L}{32} \qquad \text{(41)}$$

Eqs. 7 become:

$$\Delta_a = \frac{P}{64}\Bigg[\int_0^{L/2} \frac{1}{E\,I}\left(-\,28\,x^2 + \frac{60}{L}\,x^3 + 2\,L\,x\right)dx + \int_{L/2}^{L} \frac{1}{E\,I}\left(-\,92\,x^2 + \frac{60}{L}\,x^3 + 34\,L\,x\right)dx\Bigg] \qquad \text{(42a)}$$

$$\Delta_b = \frac{P}{64}\Bigg[\int_0^{L/2} \frac{1}{E\,I}\left(120\,f\,\frac{x^2}{L} - 352\,f\,\frac{x^3}{L^2} + 240\,f\,\frac{x^4}{L^3} - 8\,f\,x\right)dx + \int_{L/2}^{L} \frac{1}{E\,I}\left(504\,f\,\frac{x^2}{L} - 608\,f\,\frac{x^3}{L^2} + 240\,f\,\frac{x^4}{L^3} - 136\,f\,x\right)dx\Bigg] \qquad \text{(42b)}$$

and

$$\Delta_c = \frac{P}{64}\Bigg[\int_0^{L/2} \frac{1}{E\,I}\left(-\,28\,x + 60\,\frac{x^2}{L} + 2\,L\right)dx + \int_{L/2}^{L} \left(-\,92\,x + 60\,\frac{x^2}{L} + 34\,L\right)dx\Bigg] \qquad \text{(42c)}$$

Completing the process, the writer found the maximum variations of the indeterminate quantities to be:

$$dX_a\,(\max) = 0.187\,i\,X_a \qquad \text{(43a)}$$

$$dX_b\,(\max) = 1.59\,i\,X_b \qquad \text{(43b)}$$

and

$$dX_c\,(\max) = 1.92\,i\,X_c \qquad \text{(43c)}$$

Generally, in order to obtain the maximum variation, the values of the elastic variables in a parabolic arch with a concentrated center load should be increased from the left abutment to 0.1 L, decreased from 0.1 L to 0.4 L, increased from 0.4 L to 0.6 L, decreased from 0.6 L to 0.9 L, and increased from 0.9 L to the right abutment.

The sensitivity coefficients found are very high for both the horizontal thrust and the moment at the springing, and—to the writer—unexpectedly low for the vertical reaction. Altogether, the parabolic arch appears to be sensitive to elastic variations to a very considerable degree, and a close control of the concrete mixture, in the case of a masonry arch, and of the dimensions, seems advisable.

JOSEPH A. WISE,[7] M. AM. SOC. C. E.—The fundamental principles of the effect of the variation of elastic characteristics and their application to specific structures are well presented in this excellent paper. In the analysis given by the author, a statically determinate basic structure is taken, and the n redundant stresses are superimposed upon it. If, instead, a statically indeterminate basic structure is used (one having $n - 1$ redundants, such as is used in obtaining an influence line for the nth redundant), the computations are simplified and some new and interesting relationships appear. In effect, this reduces all structures to singly redundant types, assuming that the remaining redundants have been determined. To avoid introducing new and possibly confusing nomenclature, the symbols used in Professor Hrennikoff's paper will be adhered to, but with the understanding that the moments, M_o, refer to moments due to the given loading in the $(n - 1)$-degree statically indeterminate base structure, and the moments m_a are those in the same base structure due to a unit load applied in place of the nth redundant. Thus, the only difference from a singly redundant structure is that the moments M_o and m_a must be calculated for an $(n - 1)$-degree statically indeterminate structure instead of being determined by statics alone.

The analysis first will be made for structures subjected to bending alone. Then, in general:

$$X_a = -\frac{\delta_{ao}}{\delta_{aa}} \qquad \text{(44)}$$

$$dX_a = -\frac{1}{\delta_{aa}}\left(d\delta_{ao} - \frac{\delta_{ao}}{\delta_{aa}}\, d\delta_{aa}\right) \qquad \text{(20a)}$$

and

$$dX_a\,(\max) = \frac{i}{\delta_{aa}}\int\left|\left(\frac{M_o\, m_a}{E\,I} + X_a\,\frac{m^2_a}{E\,I}\right)\right| ds \qquad \text{(20b)}$$

Eq. 20*b* also can be written:

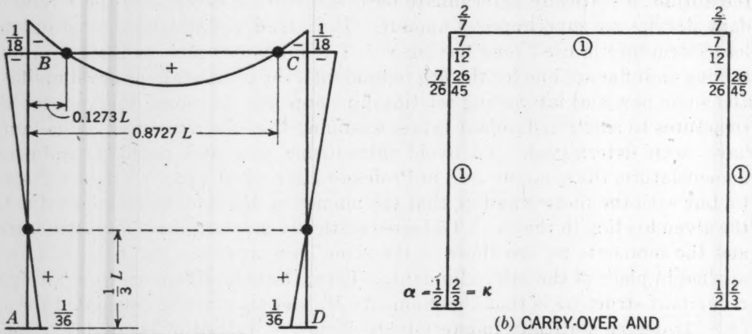
$$dX_a\,(\max) = \frac{i}{\delta_{aa}}\int\left|\frac{(M_o + X_a\, m_a)\, m_a}{E\,I}\right| ds = \frac{i}{\delta_{aa}}\int\left|\frac{M\; m_a\, ds}{E\,I}\right| \qquad \text{(45)}$$

---

[7] Lt.-Comdr. (CEC), U.S.N.R., Care, Public Works Office, 3rd Naval Dist., New York, N. Y.; and Assoc. Prof. of Structural Eng., Univ. of Minnesota, Minneapolis, Minn. (on leave).

in which M is the final or true moment at any segment, ds, and is equal to $M_o + X_a\, m_a$. Eq. 45 shows that dX_a will have a zero value (that is, a change in $E\,I$ in a segment ds will not change X_a) when either M or m_a is zero. In integrating along the members of the structure, whenever either M or m_a passes through zero the integrand changes sign; hence, the segments between these null points are alternately increased and decreased in $E\,I$. If M and m_a should happen to have a common null point, this null point is omitted, since both change sign in passing through it. Thus, a general rule could be formulated as follows:

> If it is desired to find the maximum variation dX_a of the moment at a point in a structure, determine the actual moments M at all points. Then consider the redundant X_a to be replaced by a pair of unit couples acting in the same sense, and determine the moments m_a in the otherwise unloaded statically indeterminate base structure. Determine the null points; then compute dX_a from Eq. 45, integrating between singular null points.



(a) MOMENT DIAGRAM

(b) CARRY-OVER AND DISTRIBUTION COEFFICIENTS

FIG. 10

This analysis can be readily extended to structures with axially stressed members, as indicated by Professor Hrennikoff, so that Eq. 45 becomes:

$$dX_a = \frac{i}{\delta_{aa}} \sum \left| \frac{N\, n_a\, L}{E\, A} \right| \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

It is obvious that members having N and n_a of like sign must be increased in area, and the other members must be decreased in area (or in $E\,A$) to obtain the greatest increase, dX_a.

To illustrate the application of the foregoing principle, the frame of Fig. 1 will be analyzed. The writer has used a precise moment-distribution method[8] in the analysis, as it gives accurate results with rapidity, but any method could be used to obtain the same results. Fig. 10 shows the actual moments M at ends of all members, and the moment diagram. The null points determined by this method are shown by heavy dots. The moment at point B is expressed by

---

[8] "A Precise Moment Distribution Method," by Joseph A. Wise, *Journal*, A.C.I., November, 1938, p. 93.

$$|M_B| = \frac{w\,L^2}{12} \times \frac{3 \times \frac{2}{7}\left(1 - \frac{2}{7}\right)}{1 - \frac{2}{7} \times \frac{2}{7}} = \frac{w\,L^2}{18} \ldots\ldots\ldots\ldots (47)$$

Fig. 11 shows the analysis for m_a. Here the moment at point B is taken as the redundant X_a and the frame is analyzed for unit couples applied as shown.

FIG. 11

Fig. 11(*a*) gives the first moment distribution, assuming no sidesway; Fig. 11(*b*) gives the precise carry-over and distribution coefficients; Fig. 11(*c*) gives moments due to an assumed sidesway; and Fig. 11(*d*) gives moments corrected for sidesway. The moment at point A, for example, is $-\frac{1}{2} + \frac{27}{23} \times \frac{1}{2} = +\frac{2}{23}$. Fig. 11 locates another null point. These null points agree substantially with those determined in the paper.

If the equations for M and m_a are written for the three parts of the frame:

Left leg—

$$M = \frac{w\,L^2}{36}\left(1 - 3\,\frac{y}{L}\right) \qquad \text{(48}a\text{)}$$

$$m_a = \frac{1}{23}\left(2 + 21\,\frac{y}{L}\right) \qquad \text{(48}b\text{)}$$

$$M\,m_a = \frac{w\,L^2}{828}\left(2 + 15\,\frac{y}{L} - 63\,\frac{y^2}{L^2}\right) \qquad \text{(48}c\text{)}$$

Beam—

$$M = \frac{w\,L^2}{18}\left(9\,\frac{x}{L} - 9\,\frac{x^2}{L^2} - 1\right) \qquad \text{(49}a\text{)}$$

$$m_a = -\frac{1}{23}\left(23 - 18\,\frac{x}{L}\right) \qquad \text{(49}b\text{)}$$

$$M\,m_a = \frac{w\,L^2}{414}\left(23 - 225\,\frac{x}{L} + 369\,\frac{x^2}{L^2} - 162\,\frac{x^3}{L^3}\right) \qquad \text{(49}c\text{)}$$

Right leg—

$$M = \frac{w\,L^2}{36}\left(1 - 3\,\frac{y}{L}\right) \qquad \text{(50}a\text{)}$$

$$m_a = \frac{1}{23}\left(21\,\frac{y}{L} - 16\right) \qquad \text{(50}b\text{)}$$

$$M\,m_a = \frac{w\,L^2}{828}\left(-16 + 69\,\frac{y}{L} - 63\,\frac{y^2}{L^2}\right) \qquad \text{(50}c\text{)}$$

and

$$\delta_{aa} = \int \frac{m^2{}_a\,ds}{E\,I} = \frac{1}{529}\left[\int_0^L \left(2 + 21\,\frac{y}{L}\right)^2 dy + \int_0^L \left(23 - 18\,\frac{x}{L}\right)^2 dx + \int_0^L \left(21\,\frac{y}{L} - 16\right)^2 dy\right] = \frac{21\,L}{23\,E\,I} \qquad \text{(51)}$$

Substituting in Eq. 45,

$$dX_a = \frac{w\,L^2\,i}{756}\left[\int_0^L \left|2 + \frac{15\,y}{L} - \frac{63\,y^2}{L^2}\right| d\left(\frac{y}{L}\right) + 2\int_0^L \left|-23 + \frac{225\,x}{L} - \frac{369\,x^2}{L^2} + \frac{162\,x^3}{L^3}\right| d\left(\frac{x}{L}\right) + \int_0^L \left|-16 + \frac{69\,y}{L} - \frac{63\,y^2}{L^2}\right| d\left(\frac{y}{L}\right)\right] \qquad \text{(52)}$$

This agrees exactly with Eq. 30*a*. However, the null points have already been found, and it is only necessary to evaluate Eq. 52 between these null points. The result will be the same as in the paper.

From a study of Eq. 45 it will be seen that dX_a will be most affected by changes in $E\,I$ where the product $M\,m_a$ is a maximum and, by obtaining the maximum of each of the three terms in Eq. 52, it will be found that the most sensitive points in the frame are: Left leg, $\frac{y}{L} = \frac{5}{42}$; beam, $\frac{x}{L} = 0.386$; and right leg, $\frac{y}{L} = \frac{23}{42}$. Thus, a curve $M\,m_a$ could reveal the parts of the structure in which changes in $E\,I$ have the greatest effect on X_a. In the demolition of structures it might be quite useful to have this information. Also, if the $M\,m_a$-curve is plotted, a planimeter could be used to obtain the mechanical integration of Eq. 45.

The approximate integration by finite summation can be easily applied to this analysis. The frame of Fig. 5 is analyzed, as in the paper, by substituting the numerical values from Table 2:

$$dH = \frac{5{,}004}{1{,}201}\,w\,i = 4.17\,w\,i \qquad (53)$$

TABLE 2.—ALTERNATE SOLUTION FOR *dH* (MAX), FIG. 4

In comparing the moment at the crown and the moment at the knee of this frame, it is noted that the two m_a-diagrams are the same and, since M is obviously the same for both cases, the variation of dX_a will be the same for both. However, in obtaining K, dX_a is divided by X_a for each of the respective cases, and for the moment at the crown, $|X_a| = 63.86$, whereas, for the moment at the knee, $|X_a| = 248.64$. Therefore, the K-values for these two points should be inversely proportional to the respective moments, or K (knee) is to K (crown) as 63.86 is to 248.64. The respective values for K—0.269 and 1.048—given in the paper agree with this ratio. From this it can be concluded that K tends to be largest where stresses are smallest. In fact, if one were to investigate a point of inflection in the structure, where X_a is zero, one would find K becoming infinite, as it obviously should, since any change in $E\,I$ elsewhere in the structure would result in a moment at this point where no moment had existed previously. Thus, it appears that K is not entirely satisfactory as a measure of the sensitivity of the structure to changes in the elastic constants. The designer is not much concerned about changes in moment where the moments are small and the stresses are far below the allowable working stresses. It is suggested that a factor

$$K' = K\,\frac{f_a}{f_w} \qquad (54)$$

be used as a measure of sensitivity, in which f_a is the actual maximum fiber stress in the structure at the location of the redundant and f_w is the allowable working stress. At points of inflection K' would be indeterminate, being of the form $\infty \times 0$, and would not be considered as significant.

The suggestion made by Professor Hrennikoff that sensitivity appears to increase as the number of static unknowns increase can be explained at least partly by the fact that, in general, as the redundancy of the structure increases, its stiffness increases, so that the deflections due to unit couples, δ_{aa}, decrease. Since this term appears in the denominator of Eq. 45, a decrease in it will cause an increase in dX_a.

The opinions or assertions contained herein are the private ones of the writer and are not to be construed as official or reflecting the views of the Navy Department or the naval service at large.

A. Hrennikoff,[9] Assoc. M. Am. Soc. C. E.—In Fig. 8 Professor Finlay has plotted the graphs of the functions under the integral signs in the expressions for the variations of static unknowns in the three-legged frame of Fig. 1. These curves depict the effect of the variation of an elastic characteristic, at different points of the structure, on the values of three static unknowns, and they may be called the "variation lines." "Influence lines" might be a better term, but it would be unsuitable because it would disagree with the generally accepted meaning of this term. The influence line gives the value of a stress quantity for different positions of a unit load; the variation line, on the other hand, shows the change in a statically indeterminate quantity for different locations of the variation of an elastic characteristic, while the loading remains the same. For each static unknown there is a distinct variation line for every loading.

If an elastic characteristic undergoes a change i' at some location with an abscissa s on the length ds, the corresponding variation of the unknown is equal to the product of i', ds, and the ordinate of the variation line at the abscissa s. (There is also an additional constant factor, $\frac{1}{D}$, that can be brought into the expression for the variation line, as may be seen from Eq. 14.)

Variation lines are useful not only as a pictorial representation of the component parts of the variations contributed by different parts of the structure, but also as a means of determining, with some exercise of judgment, the probable variations of the unknowns, as distinct from the extreme values expressed by Eq. 15.

Professor Finlay has made use of these curves in his investigation of possible variations of stress quantities due to the frame cracking in the vicinity of points with high bending moments. In the structure considered, this effect proved to be very low; however, as the discusser correctly states, this may not be true in general.

The writer agrees with Mr. Fraenkel that practical applicability of the method considered may be confined to reinforced-concrete structures, in which the variations of the modulus of elasticity and of the moment of inertia may be quite substantial. In this connection, Mr. Fraenkel's suggestion to investigate the actual behavior of the structure as built, on the basis of tests of concrete specimens, taken from different parts of the structure, is quite appropriate, provided the test cylinders are made truly representative of the quality of concrete in the structure itself.

---

[9] Asst. Prof., Civ. Eng., Dept. of Civ. Eng., Univ. of British Columbia, Vancouver, B. C., Canada.

The writer prefers to differ with the discusser on the question of the suitability of varying the working stresses in reinforced-concrete structures as functions of sensitivity coefficients. In spite of Mr. Fraenkel's objections, the writer still thinks that even if such departure from the current practice might add to the complexity of design, the high values of sensitivity coefficients frequently occurring even in common structures, such as the one analyzed by Mr. Fraenkel, should make this measure quite in order, when designing structures of considerable importance.

Commander Wise has made an important contribution to the theory of the variation of statically indeterminate quantities by his illuminating interpretation of the significance of the expression for, what was termed herein, the "variation line." Eq. 45 is presented by Commander Wise in lieu of Eq. 15, as being applicable to structures with flexural stress. In this formula, M signifies the actual moments in the given structure with n static unknowns under the given loading, whereas m_a and δ_{aa}, respectively, represent the moments and the relative movement produced by a pair of stress quantities $X_a = 1$, in a modified structure with $(n - 1)$ unknowns, obtained from the given structure by removal of the restraint corresponding to X_a. This statement with regard to restraint should be understood in the following sense: If X_a signifies a bending moment at a point A, this modified structure should be assumed capable of a relative rotation, but not of a linear separation, of the two parts of it at this point; in other words, a pin is assumed to be inserted at the point A. On the other hand, if X_a signifies a shear, then the two parts of the structure are assumed capable of separating at the point A in the direction normal to the axis, while no tangential or angular relative movement is permitted at this point.

Eq. 45, proposed by Commander Wise, possesses the following advantages over the original Eq. 15:

1. It is simpler in form;
2. It illustrates the mechanical significance of the integrand, and thus can be computed by any suitable method, giving the values of M and m_a; and
3. It affords a better means of determining the null points of the integrand by equating to zero the expressions for M and m_a separately, rather than the product of these functions, which naturally has a more complex form.

Eq. 45 shows clearly why the variation line corresponding to the sum of two loadings acting simultaneously can be found by superposition of the two variation lines of the separate loadings. The reason for this relationship is that the expression m_a is the same in all three loadings, whereas the moment curve M of the combined loading is equal to the algebraic sum of the moment curves of the two separate loadings. The null points of the variation line of the combined loading, that come from m_a, are the same as in the separate loadings, whereas the null points produced by M are generally different in the three loadings considered.

The advantages of Eq. 45, demonstrated by Commander Wise and elaborated in the preceding paragraphs, make the inclusion of this equation into the theory of variation of static unknowns very desirable.

The counterpart of Eq. 45 applicable to structures with axial stresses has been given by Commander Wise in the form of Eq. 46. The significance of the normal stresses N and n_a in this equation is analogous to the significance of the moments M and m_a in Eq. 45.

Commander Wise suggests that the expression for the sensitivity coefficient K be modified by multiplying it by the ratio of the allowable and the actual unit stresses. The writer does not think that this modification would be of any advantage in the design, since the values of the variations need only be calculated for the stress quantities governing the design, in application to which the proposed modifying factor would always be not far from unity.

The writer is grateful to all the discussers for their contributions.

Paper No. 2182

BASIC ECONOMIC CONSIDERATIONS AFFECTING SINGLE AND MULTIPLE PURPOSE PROJECTS

By Otis M. Page,[1] M. Am. Soc. C. E.

With Discussion by G. B. Pillsbury, M. Am. Soc. C. E.

Synopsis

A practical analysis of a given condition is followed throughout the paper. The writer has defined an exemplary area and discusses data collected as a result of field investigations. The paper is subdivided into two sections in discussing single and multiple purpose projects.

SECTION I.—ANALYSIS OF DATA, FLOOD-CONTROL PROJECTS

1. Introduction

This subject is so complicated that scarcely any set rules are applicable in all cases. For this reason, an exemplification is made of what may be encountered in the collection of flood damage data, and in the determination of the benefits that may result from the construction of proposed flood protection works. The actual collection of data in the field by experienced investigators cannot be stressed too strongly. It matters not what interpretation may be placed on "direct" or "indirect" damages or benefits; if the basic data are not a true representation of facts, the ultimate answer may be much in error.

2. Direct Benefits

Direct benefits resolve themselves into one question: What benefit in dollars and cents will accrue to the owners and others affected? It does not make any difference whether the owners "cash in" now or wait and receive the benefits when such benefits materialize. They may assume many forms, depending on the adaptability of the particular ownership to benefit. A farm may have partial or total flood protection as a result of protective works; woodlands in either case may be improved from nonagricultural to agricultural lands and, likewise, properties unsuited for industries may be made proper locations for industries. The same condition holds true relative to residential and other uses. The item, "direct net flood losses prevented" on certain agricultural

---

Note.—Published in March, 1942, *Proceedings*.

[1] Col., Corps of Engrs., U. S. Army, Care, Adjutant Gen., Washington, D. C.

properties is a function of benefit, but flood losses on properties cannot be capitalized where there are no flood losses. For example, lands may become industrial properties because of flood protection; or, as a result of flood protection, pasture or ranch lands may be converted to higher agricultural use. In many cases, woodlands and wild grass meadow pastures are benefited by occasional overflows. It may be noted, therefore, that the application of a single rule is not feasible. Different rules and methods must be applied to meet the conditions or, in other words, "every tub must stand on its own bottom." In this connection, every report should be a compendium of the actual field facts based on actual inspection by qualified field men. Guesswork, even on a preliminary examination, should not be accepted. It appears evident that direct benefits should be measured along the following general lines:

(*a*) Take credit for all direct prevented net flood losses (crops, buildings, livestock, or other tangibles), after flood protection, hereafter referred to as Item 2(*a*).

(*b*) Take credit for any additional direct net flood losses prevented that may ensue as a result of clearing or conversion of lands to a higher use after flood protection, hereafter referred to as Item 2(*b*).

Discussing these two benefits, Item 2(*a*) should be susceptible of close estimation by the use of proper field personnel making use of existing factual data; Item 2(*b*) involves an element of speculation or guess. A close study of the economic conditions, in general, in the affected area should be made. The unbiased opinions of reputable businessmen and farmers will be of great assistance. Under Item 2(*b*), abstract considerations are involved, and care should be taken to avoid the consideration of Utopian ideas. Credit should not be taken for benefits from developments that could occur only after flood protection is provided as an item of flood losses prevented. The sum total of remaining benefits in the form of flood losses prevented will be taken care of under Item 2(*b*). Simplification of considerations is important. Field men should not be asked to perform the impossible and draw fine-cut lines, thereby producing a distribution that serves no useful purpose.

3. Calculation of Losses and Benefits

Under Item 2(*a*), all flood losses may be reduced to an annual basis and this, in turn, may be capitalized for the increment of value as a result of flood losses prevented. The rate of capitalization should be variable to reflect risks accurately. For example, an area with only partial flood protection will carry a higher rate than one with complete flood protection. Furthermore, this phase of the situation deals with a farmer's or businessman's dollar and should carry a higher rate than consideration of public funds. Consideration is given now to benefits to individuals. For example, *A* applies to a Land Bank or other agency for a loan. His average annual net income is $500 from his farm or property. If $500 is capitalized at 5%, $10,000 is the value of his farm. Does the Land Bank or loaning agency value this farm or property at

$10,000? In all probability it does not, as it will use from 6% to 15% as a rate for capitalization, making the value range from $3,333 to $8,333, which is more in line for a property with a net income of $500 per year. There is an economic consideration to be given capitalization rates that cannot be ignored; and 10% appears to be normally about the correct rate to apply if abnormal hazards are not involved. This discussion refers to increased value by capitalizing the value of prevented flood losses. In applying capitalization to obtain the increment of increase in value, the entire operation must be analyzed to determine exactly what this prevented loss means to the individual in net gain on an operation. (This is a long discussion within itself and will be omitted here.)

Under Item 2(*b*), "annual flood losses prevented" do not apply, and to apply would be erroneous. The benefit must be taken care of by anticipated enhancement in value. It makes no difference whether the owner sells or holds his property, the problem is to determine the present worth of this increase in value. This will be the "benefit." It represents a "capital sum," and it can be reduced to an annual benefit. The question that may present itself is: What about prevented flood losses on lands converted to higher use as a result of flood protection? For instance, a factory or dwelling is built on property falling under Item 2(*b*), and this property is protected from flood losses as a result of the project. In the first place, the owner purchased or already possessed the land. If he purchased it, he paid the increased benefit price obtained as a result of flood protection, and the seller received a capital benefit. If he happened to be the original owner under the project, he has reaped a benefit in like measure. Pursuing the question further: The factory or house is benefiting by the flood protection. However, the house or factory owner has paid the price he would pay in a flood-free area. Therefore, any increased benefits to this house or factory as a result of prevented flood loss must be in the indirect classification. Otherwise, there will be duplication. It should be borne in mind, also, that enhancement due to change in land use that would have occurred if no protection or additional protection had taken place cannot be considered as a project benefit. Although, for the purposes of exemplification, a case is used in which the trend justifies the consideration of future development, no credit is taken nor should be taken on this development for flood losses prevented or for capital gains. Schedule *B*, the "as is, where is" value which represents the average value of the property without flood protection for the same period as the period of proposed flood protection, is used as the basis for determining the proposed project benefits. Observation has been rather conclusive that, in areas in need of flood protection, developments are usually at a standstill, or going backward. It is believed that a *status quo* condition is likely to hold true in most cases in future years as the population of the United States is expected to reach a stationary level within twenty or twenty-five years. Further, the trend toward the elimination of marginal and submarginal lands from private use will probably continue. Many other valid reasons can be enumerated.

4. SUMMARY

Direct benefits equal flood losses prevented, plus present worth of enhancement brought about by changed use or potential changed use; or, direct benefits = Item 2(*a*) + Item 2(*b*).

5. EXAMPLE OF APPLICATION

TABLE 1.—AVERAGE CLASSIFICATION (SCHEDULE *A*) OF 640 ACRES IN A PROPOSED FLOOD-CONTROL AREA

No.	No. of acres	Unit value (dollars per acre)	Value (dollars)
a	100	90.00	9,000
b	100	70.00	7,000
c	100	30.00	3,000
d	100	12.50	1,250
e	140	7.50	1,050
f	100	4.00	400
g	Buildings and improvements		6,300
	640	Total value	28,000

TABLE 2.—AVERAGE CONDITIONS OF THE PROPERTY WITHOUT FLOOD PROTECTION (SCHEDULE *B*)

No.	Description	Acres	Dollars per acre	Total value (dollars)
a	Cleared and in cultivation, subject to slight flood damage	100	100	10,000
b	Cleared and in cultivation, subject to considerable flood damage	120	75	9,000
c	Cleared and in cultivation, subject to heavy flood damage	180	45	8,100
d	Pasture land, largely meadow; cleared but too severely flooded to cultivate	100	15	1,500
e	Woodland; can be cleared (potential) but has severe flood hazard	40	10	400
f	Nonagricultural woodland; too low to drain, or has poor soil; cannot be considered agricultural land if protected; a timber-growing or pasture proposition, or both	100	5	500
g	Building and all-improvement value on entire tract	..	..	6,500
	Total value	..	..	36,000

An exaggerated case is taken to attempt to emphasize various considerations in the foregoing discussion. Taking the case of an area of 640 acres owned by an individual or group of individuals in a proposed flood-control area, the "as is, where is" classification and value of this area are given in Table 1. It is entirely probable that conditions may be such that the present "as is, where is" setup should be used as the basis for determining the proposed project benefits. As previously expressed, one is injecting an element of guess or prophecy in estimating a development trend for the area since he must know what periods in the past will be representative of the future. Fifty years hence is a long time to project a curve of this nature, with the uncertain or vague data as to what has happened in the past. Fluctuations in real estate and commodity prices are beyond accurate estimation. It might be emphasized further that agricultural development during the past eight years has been confined generally to new areas, whereas the trend points toward retrogression in the older areas. However, in the case being exemplified, the development trends exist, and they are reflected in Table 2, which represents the average conditions of the property without flood protection for the same period as the proposed project life, which is fifty years in this case. This schedule is the appraisal of the average value of the property without flood protection for the same period as the period of proposed flood protection, and it is used as the basis for determining the proposed project benefits. Since complete flood protection is offered in this case, the following conclusions are reached from a study of the area in Schedule *B*:

Item a.—All of this area, when protected, will receive benefits through direct flood losses prevented.

Item b.—Due to very favorable location, 20 acres of this area, when protected, will have great potentiality for suburban home sites and will convert to higher use. Therefore, 20 acres will receive a capital gain, leaving 100 acres to receive benefits through direct flood losses prevented.

Item c.—Due to location and shipping facilities, 20 acres of this area, when protected, will have great potentiality as industrial property. These 20 acres will receive a capital gain, and the remaining 160 acres will receive benefits through direct flood losses prevented.

Item d.—This area has only a small flood loss and, when protected, it will remain in *status quo* as pasture land, because the owner requires that much acreage in pasture. Due to the nature of the soils and to insufficient drainage facilities, pasturage is its highest and best use. By the elimination of flood hazards, an increase in the number of livestock ranging on this land can be expected. To use both of these benefits would be duplication. The greater benefit (in this case, benefit through flood losses prevented) should be taken.

Item e.—No appreciable flood losses occur on this area; however, when protected, it will receive a capital gain due to flood protection, because the protection will render it more suitable for cultivation and will improve logging conditions in case the owner retains it in woodland. Consequently, the market value will be increased, thereby effecting a capital gain.

Item f.—On this area flood losses are virtually nothing, and due to soils and the lack of drainage facilities, the land is nonpotential or nonagricultural and will remain in this classification after flood protection. However, when protected, the market value will be increases as a timber-growing proposition, due to more favorable logging conditions, and the area will be more valuable as a woods range for livestock. This area, therefore, will receive a small capital gain.

Item g.—These improvements will create benefits either as capital gains or as flood losses prevented; the greater benefit should govern. In this case, the buildings are located principally on high ground. Little use is being made of some of the buildings, and their value to the farm is little more than salvage value. When the area is protected, these improvements will convert the land to maximum use. Consequently, their value to the farm will increase; this will be a capital gain. This example is selected for exemplification, and it is, no doubt, an unusual case. In most instances, Item *g* would receive a greater benefit from flood losses prevented, putting it under Item 2(*a*), than from capital gain.

From the foregoing conclusions, the appraisal of the average value of the property for the period of protection is given in Table 3. The increase in the value of the area of Items *a*, *b*, *c*, and *d* of Schedule *C* (Table 3) over the value of the same acreage of Schedule *B* (Table 2) is due to flood losses prevented, and the increase in the value of the remaining area of Schedule *C* over the value of the same acreage of Schedule *B* is due to enhancement in value as a result of changed use or potential changed use. These differences are indicated in Table 4.

TABLE 3.—AVERAGE VALUE OF PROPERTY FOR A GIVEN PERIOD OF PROTECTION (SCHEDULE *C*)

No.	Acres	Dollars per acre	Value (dollars)
a	100	110.00	11,000
b	100	100.00	10,000
c	160	65.00	10,400
d	100	17.50	1,750
e	40	12.00	480
f	100	6.00	600
g	20	200.00	4,000
h	20	175.00	3,500
i	Buildings and improvements		7,170
	640	(Total)	48,900

The enhancement in Items *a*, *b*, *c*, and *d* of Table 4 may not always represent annual flood losses capitalized. The average annual flood losses prevented must be determined from data secured in the area under consideration. In this case, the sum is estimated to be $625.00 (see heading "Summary"). By the construction of proposed flood-control works, the area considered would receive an annual benefit of $625 through average annual flood losses prevented and a total capital gain through flood protection of $5,950. Assuming the life of the project to be fifty years, the present worth of this capital gain of $5,950 would be $5,291.27, using 4.5% rate of interest. The annual benefit of $5,291.27, at 4.5%, would be $238.11. The total direct annual benefit, therefore, would be $625.00 plus $238.11, which equals $863.11.

TABLE 4.—DIFFERENCES DUE TO FLOOD LOSSES PREVENTED, AND INCREASE IN VALUE OF REMAINING AREAS

No.	Enhancement by Prevented Flood Losses		Capital Gain	
	Acreage	Dollars	Acreage	Dollars
a	100	1,000	....	....
b	100	2,500	....	....
c	160	3,200	....	....
d	100	250	....	....
e	....	....	40	80
f	....	....	100	100
g	....	....	20	2,500
h	....	....	20	2,600
i	....	....	....	670
....	460	6,950	180	5,950

6. DIRECT FLOOD LOSSES (OTHER ITEMS)

Other items of flood damage are numerous, such as damage to livestock, seed, feed, and implements, the cost of exodus and reoccupation, damage to business operation through curtailment, inability to fulfil contracts, increased overhead, and damage to chattels of all kinds not heretofore mentioned. In some cases, there may be labor losses but, in such cases, considerable care should be taken not to duplicate this item with indirect losses applying to the area as a whole. The aforementioned losses usually may be cataloged and treated under Item 2(*a*) (flood losses prevented). However, other than farming operations, these losses can best be handled separately and may (and usually do) consist of both Item 2(*a*) (flood losses prevented) and Item 2(*b*) (outright capital gains as a result of flood protection). Other direct flood losses may consist of physical damage to highways, railroads, and utilities of all kinds and also, when justified, cost borne by federal, state or quasi-public or private agencies in flood fighting and relief work of all kinds, including exodus and reoccupation. Ordinarily, these losses will fall under Item (2*a*) (flood losses prevented).

7. Indirect Flood Losses

No doubt more care should be exercised in the evaluation of indirect flood losses than in dealing with direct losses. Certainly, more experience is required, because the appraiser must have a clear economic picture of the area as a whole. In no sense can justification be found whereby an arbitrary percentage of direct flood losses can be taken as a correct value for indirect losses. Usually, these losses are not inventoried as easily as direct losses where there are factual data available as a result of prior floods. In most cases, the principal items would consist of: (1) Inconvenience caused by disruption of the functioning of railroads, highways, and utilities with the attendant monetary losses; (2) economic losses to the community as a whole on account of business cessation or disruption not specifically included in direct losses; (3) any increased cost of medical care not included in indirect losses; and (4) labor losses as affecting the community as a whole and not cataloged under direct losses. Consideration should be given to the cost of extra labor used in rehabilitation as an offsetting factor. Contiguous and sometimes remote areas may be materially benefited. However, as a result of a project, consideration should be given to the economic effect of taking large areas out of productive use, and

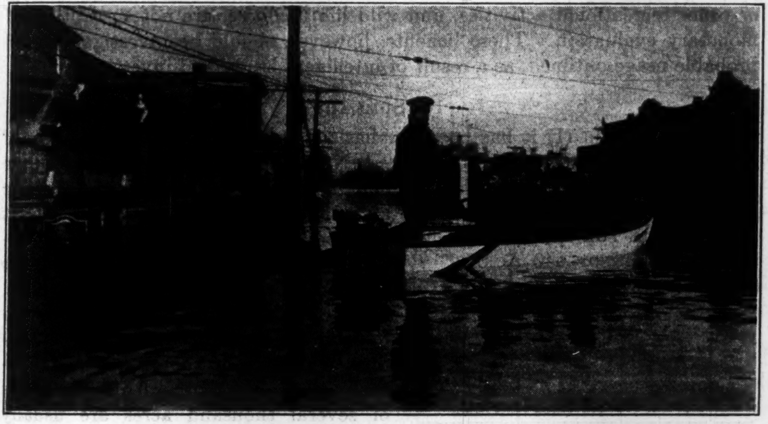

Fig. 1.—Among Indirect Flood Damages Are the Economic Losses to the Community as a Whole on Account of Business Cessation or Disruption

out of taxation. If credit is fully taken for community benefits in indirect benefits, it would appear that proper charge should be made at least for any reimbursement the federal government would make to political units as a result of property taken out of taxation. One can readily see that real field fact-finding must be resorted to in order to form any kind of intelligent estimate of this situation which, for purposes of convenience, is placed under the same heading as "Indirect Losses." The benefit is more suitably cataloged under "Capital Gains."

8. INTANGIBLE LOSSES

Certain flood losses or inconveniences are not susceptible of evaluation in dollars and cents. In this category may be loss of human life and the abnormal spread of disease affecting the health and happiness of inhabitants, disruption of schools and religious assemblies, burial of the dead, and, perhaps, many other inconveniences of more or less importance to a specific community.

9. INTANGIBLE BENEFITS

Benefits accruing to the community, county, state, or nation, as a result of project works according recreational facilities such as hunting, fishing, bathing, or other recreational activities, and wild life facilities, are not susceptible of monetary evaluation. These benefits, however, should be investigated, and probable usage outlined, as a result of intelligent study and investigation.

10. SUMMARY

In this section (I) it has been emphasized that the accurate collection of field data is of paramount importance. No detailed discussion of technique and method is outlined as this is quite an extended discussion within itself. It may be well to mention here that ordinarily a much greater zone or segment of a proposed project would be studied as an entity than is exemplified in the foregoing, depending upon varying conditions of terrain as related to topography, culture, and other features. Belts of several thousand acres are usually inspected in the field and data are compiled, using the most convenient and applicable methods. Technique and method used in the field will be largely governed by maps and other data available and the degree of accuracy required in the findings. It is emphasized that the damage and valuation figures presented in Section I must be based actually on field data obtained by competent personnel.

TABLE 5.—ANNUAL DIRECT BENEFITS FOR EACH CLASSIFICATION OF 640 ACRES EXEMPLIFIED

No.	Acreage	Average Annual Benefits Through:	
		Losses prevented	Capital gain
a	100	$ 85.00	$ 40.02
b	100	225.00	100.05
c	160	300.00	128.06
d	100	15.00	10.00
e	40	0	3.20
f	100	0	4.00
g	20	45.00	100.05
h	20	37.50	104.05
i	....	20.00	26.81
....	640	$727.50	$516.24

Annual direct benefits of $625 through flood losses prevented were determined from field data. Table 5 gives the annual direct benefits through flood losses prevented and through capital gain for each classification of the 640 acres exemplified. It shows that the benefits through flood losses prevented for Items *a*, *b*, *c*, and *d* are greater than the benefits through capital gain, whereas the benefits through capital gain for Items *e*, *f*, *g*, *h*, and *i* are greater than the benefit through flood losses prevented. It has been emphasized, throughout the analysis, that the greater benefit should govern. Consequently, the total average annual direct benefits would be as follows:

Average annual direct benefits due to:	
Flood losses prevented = Items *a*, *b*, *c*, and *d*	$625.00
Capital gain = Items *e*, *f*, *g*, *h*, and *i*	238.11
Total average annual direct benefits	$863.11

Conclusion.—On the area of 640 acres exemplified, flood protection would result in a direct annual benefit of $625 and a total capital gain of $5,950. Assuming the life of the project to be 50 years, the present worth of the capital sum enhancement of $5,950, using 4.5% rate of interest, would be $5,291.27. The annual benefit of this sum would be $238.11. The total annual direct benefit, therefore, will be $625.00 plus $238.11 which equals $863.11. Before estimating indirect benefits, all of the area affected by the project must be considered. Consequently, it is not practical to make estimates of the indirect benefits on the 640 acres.

SECTION II.—MULTIPLE PURPOSE PROJECTS

Section I discusses factors affecting flood-control projects. It is possible, of course, to encounter projects wherein flood control may not be of primary importance and the other features—irrigation, power, and navigation—may all be considered in determining economic justification. The degree of flood protection afforded must be considered, of course, when combined with irrigation, power and stream regulation or navigation. For this reason it would complicate the subject, no doubt, to pursue a synthetic analysis of the property taken for exemplification under a flood-control project as outlined in Section I. The same reasoning would apply, however, in determining Schedules *A* and *B*, Section I, as heretofore. In all probability, Schedule *C* would assume a different form, depending upon how the property would be affected by the project purposes.

11. DIRECT BENEFITS

The same principles will apply in a multiple purpose project as in a single purpose project—there may be both annual direct benefits and capital gains. It must be borne in mind that duplication should be avoided and that the aggregate of the benefits from whatever sources cannot exceed the intrinsic worth of the increased value of the property due to the construction of the project works.

12. INDIRECT BENEFITS

Indirect benefits will be more far-reaching under multiple purpose projects as greater outlying areas will be affected. Plentiful and cheap power, of course, has far-reaching benefits. Water for irrigation purposes may convert large areas of cheap range lands into areas of intensified farming, bringing in settlers with all the attendant community improvements. Numerous other indirect benefits could also be enumerated.

13. Intangible Losses and Benefits

The same general principles will apply to the consideration of intangible losses and benefits as are discussed in Section I.

14. Acknowledgment

The opinions expressed in this paper are entirely the writer's responsibility and have no relationship to the official directives of any agency of the federal government. It is desired to acknowledge the services of H. E. Cox, Land Appraiser, of the Southwestern Division, U. S. Engineer Department, in checking mathematical calculations and collaborating on economic considerations.

DISCUSSION

G. B. Pillsbury,[2] **M. Am. Soc. C. E.**—A procedure is presented in this paper for evaluating the economic benefits from proposed projects intended wholly or partly for flood prevention. The applicability of the procedure obviously depends upon the purpose that the investigation is to serve. An evaluation of flood-prevention benefits conceivably might be made for a large landholder, or group of landowners, to determine whether the construction of works for the protection of the property would be profitable as a private enterprise; or it might be undertaken for a municipality or flood control district to determine whether the local benefits would justify the local taxpayers in undertaking flood protection works; or it may be undertaken to determine the economic justification from the viewpoint of the adoption of a federal flood control or multiple purpose project. The procedure presented in the paper evidently has in view this third purpose.

A prudent, or even an imprudent, private owner would be moved principally by the anticipated enhancement of the value of his property in deciding upon the advisability of investing his own funds in flood control works. This enhancement might be credited with the flood losses prevented, which are listed as Item 2(*a*) in the paper, as well as with the more profitable utilization of the land after protection, listed as Item 2(*b*), but the latter is usually the compelling consideration. In any case, he would scarcely undertake any considerable expenditure unless at least the paper profits showed a wide margin over the estimated cost. The close figuring shown in the author's example ordinarily would not have much financial appeal.

Flood control works, whether in the nature of storm drains or more extensive enterprises, ordinarily are undertaken by municipalities or local flood control districts on broad grounds of public necessity or convenience, rather than because of a detailed evaluation of financial benefits. Generally, such works are adopted either to rectify an inconvenient or intolerable situation that has grown up because of municipal development, or to prevent the recurrence of a recently experienced flood disaster. Such works are built to satisfy an insistent public demand, and a close figuring of financial benefits is not often required. In exceptional cases, to be sure, legal requirements may entail the assessment of benefits against the properties affected, and the considerations presented by the author might be applicable to the preparation of the assessment roll.

In the investigation of a proposed federal flood control project, an evaluation of the benefits is required by the Flood Control Act of June 22, 1936, in which Congress laid down the policy:

> "* * * that the Federal Government should improve or participate in the improvement of navigable waterways or their tributaries, including watersheds thereof, for flood control purposes, if the benefits to whomsoever they may accrue are in excess of the estimated costs and if the lives and social security of people are otherwise adversely affected."

---

[2] Brig.-Gen., Corps of Engrs., U. S. Army (*Retired*), Ross, Calif.; formerly Asst. Chf. of Engrs.

Sound policy undoubtedly requires that public works be undertaken only when the benefits exceed the estimated cost; but these benefits are not necessarily, nor even generally, material ones which can be evaluated by an engineering computation. The more important works contemplated by the Federal Flood Control Act are those for the prevention or mitigation of a recurrence of destructive floods which have caused loss of life as well as of property, have produced widespread inconvenience and discomfort because of the interruption of rail and highway traffic and other public services, and have inflicted suffering and misery upon the considerable number of persons who were driven from their homes. The writer does not believe it to be the intent of Congress that the justification for such projects should rest on a nice evaluation of the material benefits, but rather that the rule of reason be applied to determine, on general grounds, whether the value of benefits which cannot be definitely computed in money will exceed the estimated cost.

On the other hand, the original Flood Control Act included the authorization of a number of projects intended to remove a continuing flood hazard to agricultural lands on which the local inhabitants had exhausted their resources in attempted protection, or were unable to raise funds for the necessary works. The procedure described by the author would appear particularly applicable to the investigation of proposed projects of this character.

ANALYTICAL AND EXPERIMENTAL METHODS IN ENGINEERING SEISMOLOGY

BY M. A. BIOT,[1] ESQ.

WITH DISCUSSION BY MESSRS. GEORGE R. RICH, N. J. HOFF, MERIT P. WHITE, N. H. HECK, FRANK NEUMANN, JACOB FELD, GEORGE W. HOUSNER, HOMER M. HADLEY, ROBERT E. GLOVER, AND M. A. BIOT.

SYNOPSIS

The arithmetical steps in the computation of the spectrum are extremely lengthy. A mechanical analyzer was developed by the author at Columbia University, in New York, N. Y., to avoid this numerical work.[2] Some of the writer's earlier work with the earthquake spectrum is reviewed briefly in this paper. It also stresses engineering applications, and presents some new results, in particular regarding the effect of the foundation. Sections 1 and 2 introduce the definition of earthquake spectrum and show the results obtained for various earthquakes with the mechanical analyzer. Section 3 is a treatment of the spectrum curves obtained with the analyzer in relation to some observed facts and to the problem of stress prediction in actual structures. Section 4 considers examples of structures with more than one degree of freedom and shows how the stresses may be computed by means of the effectiveness factor. (The expression "efficiency factor" instead of "effectiveness factor" was used in the previous paper.[2]) The danger of a phenomenon referred to as the "whip effect" is also pointed out. Some attention has been given to another aspect of the problem in section 5; the effect of the foundation on the rocking motion of a rigid structure is taken into account. It is shown that in this case the same methods using a spectrum and effectiveness factors can still be applied by introducing an additional degree of freedom and a natural period corresponding to the rocking motion on the foundation.

INTRODUCTION

To a great extent the design of earthquake resistant structures is still an art based on observational facts and experience. Development of experimental

[2] "A Mechanical Analyzer for the Prediction of Earthquake Stresses," by M. A. Biot, *Bulletin*, Seismological Soc. of America, Vol. 31, No. 2, April, 1941, pp. 151–171.

and analytical approaches has been very slow partly because of the lack of accurate information on the accelerations of strong-motion earthquakes and partly because of the great complexity of the phenomena involved. This gap between the empirical and scientific approaches is being reduced constantly, leading to improvement in codes and rules for the design of quake-resistant structures. Information on strong-motion earthquakes has been made available in recent years by the valuable work of the U. S. Coast and Geodetic Survey. Pooling the data furnished by the earthquake accelerograms with existing seismological knowledge only marks the beginning of analytical and experimental investigation. To picture the phenomenon in all its complexity one must imagine that the structure to be analyzed is floating on a medium in which highly irregular waves are propagating. The structure has the attributes of distributed elasticity and damping effects. Like a ship in the ocean it does not participate completely in the motion of the surrounding medium, its motion being dependent upon its own rigidity and mass and on its size relative to the waves. Internal friction and yield point in the surrounding soil must have an important effect on resonance phenomena. Also the properties of the surface layers of the earth vary greatly with location and depth so that complicated reflection, refraction, and diffraction of the waves must be expected. This is also true for agglomeration of buildings in which case the structures themselves must have a considerable influence on the intensity and direction of the waves.

Instead of approaching this problem as an entirely complex matter it must rather be expected that a solution will emerge gradually from the careful analysis of simplified cases in which the influence of each individual factor is clearly defined and checked critically against observation.

One of the simplifications usually introduced is the assumption that the ground behaves as a shaking table, the horizontal motion of which is taken to be the same as that derived from the horizontal accelerogram of an earthquake. A basic analytical approach to this problem was developed by the author in 1932,[3, 4, 5] in which the concept of the earthquake spectrum was introduced. This is a curve characteristic of a given earthquake which gives some kind of periodicity content by associating a certain acceleration intensity with a given period. It was shown in the earlier work how this curve could be computed and how use of it could be made for the acceleration of earthquake stresses. To this purpose, the motion of the structure is considered as the superposition of its various modes of vibration and the maximum stress produced in each mode is made to depend on a coefficient characteristic of the structure and of that particular mode. This coefficient in the present paper is referred to as the effectiveness factor. The procedure permits the easy comparison between various earthquakes and between various types of structures or modes within these structures as to the stresses produced by a given earthquake.

Applications of the concept of earthquake spectrum,[6] using the writer's analytical method, have been made by R. R. Martel, M. Am. Soc. C. E., and M. P. White, Assoc. M. Am. Soc. C. E., and experiments along the same line have been made by L. S. Jacobsen and N. J. Hoff.[7]

Notation.—The letter symbols in this paper are defined where they are first introduced and are assembled for reference in the Appendix.

I.—Effect of an Earthquake on a Structure with One Degree of Freedom

Consider a mass m connected to the ground by weightless springs (Fig. 1). The horizontal displacement of the mass relative to the ground is denoted by u, and the spring rigidity is such that a horizontal force F produces a displacement

$$u = \frac{F}{k} \qquad (1)$$

The constant k is called the "spring constant."

If the ground is given a horizontal acceleration a_0 applied very gradually so that no transient oscillation occurs, the mass will assume a constant deflection:

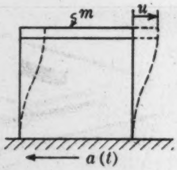

FIG. 1

$$u_0 = \frac{m\, a_0}{k} \qquad (2)$$

The total shear in the springs is then

$$V = m\, a_0 \qquad (3)$$

During an earthquake the horizontal acceleration is a function $a(t)$ of the time t. Denoting by v the displacement of the ground and neglecting the damping, the equation of motion of the mass m is

$$m \frac{d^2}{dt^2}(u + v) + k\, u = 0 \qquad (4)$$

The displacements u and v are taken positive to the right and the acceleration is taken positive to the left; hence

$$\frac{d^2 v}{dt^2} = -a(t) \qquad (5)$$

and Eq. 4 may be written

$$m \frac{d^2 u}{dt^2} + k\, u = m\, a(t) \qquad (6)$$

Eq. 6 shows that the relative displacement u obeys the differential equation of motion of a simple oscillator under the force

$$m\, a(t) = F(t) \qquad (7)$$

The earthquake is taken to start at the instant $t = 0$; the mass m being initially at rest, the relative displacement u as a function of time is given by the well-known solution[8]

[6] "Some Studies on Earthquakes and Their Effects on Structures," by R. R. Martel and M. P. White, Rept. on Earthquake Studies for Los Angeles County, Pt. I (1939) (unpublished).

[7] *Ibid.*, Pt. II.

$$u = \frac{1}{\sqrt{k\,m}} \int_0^t F(\theta) \sin \sqrt{\frac{k}{m}}\,(t - \theta)\, d\theta \quad \text{(8a)}$$

or

$$u = \frac{T}{2\,\pi} \int_0^t a(\theta) \sin \frac{2\,\pi}{T}\,(t - \theta)\, d\theta \quad \text{(8b)}$$

in which: $F(\theta)$ = force; θ = time variable of integration; and, T, the natural period of the oscillator, equals

$$T = 2\,\pi \sqrt{\frac{m}{k}} \quad \text{(9)}$$

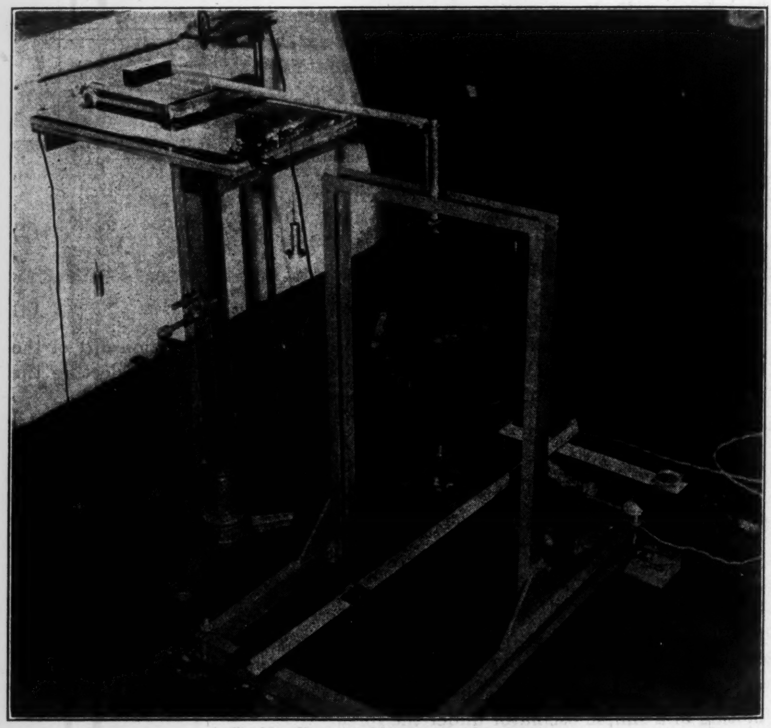

FIG. 2.—VIEW OF MECHANICAL ANALYZER

The total shear in the springs is

$$V = k\,u = m\,\frac{2\,\pi}{T} \int_0^t a(\theta) \sin \frac{2\,\pi}{T}\,(t - \theta)\, d\theta \quad \text{(10)}$$

---

[8] "Mathematical Methods in Engineering," by Theodor von Kármán and M. A. Biot, McGraw-Hill Book Co., Inc., New York, N. Y., 1940, p. 404.

The quantity:

$$f(t) = \frac{2\pi}{T}\int_0^t a(\theta)\sin\frac{2\pi}{T}(t-\theta)\,d\theta \ldots\ldots\ldots\ldots\ldots (11)$$

is a function of time which gives the complete stress history of the oscillator. That is, if the integration is performed with respect to θ between the limits 0 and t, and repeated for all values of t, a function of time is obtained which, according to Eq. 10, will give the value of the total shear V at every instant t.

II.—Earthquake Spectrum Evaluated by Means of a Mechanical Analyzer

It is of special interest to find the maximum value of the stress produced by a given earthquake. Denoting by A the maximum value of Eq. 11, the maximum shear is written

$$V_{\max} = m\,A \ldots\ldots\ldots\ldots\ldots\ldots (12)$$

Comparing with Eq. 3, one may say that, as far as the maximum shear is concerned, the effect of the earthquake is equivalent to that of a constant acceleration A applied gradually at so slow a rate that only a statical deflection is produced without the occurrence of any transient oscillation.

Of course for a given earthquake the value of A depends on the parameter appearing in Eq. 11—that is, on the natural period T of the structure. The quantity A is referred to as the "effective acceleration" of the earthquake for the period T. It will be noticed that the effective acceleration for a particular earthquake depends only on the period of the oscillator. Therefore, one may evaluate this effective acceleration for various oscillator periods and consider it to be a characteristic function $A(T)$ of the period for each particular earthquake. This function is called the "acceleration spectrum" of the earthquake. (Use has sometimes been made of the expression "equivalent acceleration" for "effective acceleration," and "oscillator response curve" or "influence line for horizontal shear" instead of "spectrum.")

The engineering significance of this concept lies in the fact that, once the spectrum is known, it is possible to write immediately the value of the maximum shear produced by the earthquake on any undamped, one-degree-of-freedom, structure. To obtain the shear produced by an earthquake in such a structure of period T the mass of the structure is multiplied by the ordinate of the spectrum for the particular value T of the abscissa. Furthermore, as will be shown, it is possible to extend the usefulness of the spectrum to structures much more complicated than the one-degree-of-freedom oscillator considered herein.

It is relatively tedious to evaluate the spectrum by analytical methods, as this would involve the calculation of the integral (Eq. 11) from a graphically given accelerogram $a(t)$ and for a great number of values of both T and t. Fortunately there are simple experimental methods by which this can be done.

A mechanical analyzer shown in Fig. 2 has been developed for this purpose. A detailed description of the apparatus was given in a previous publication.[3] It is a torsion pendulum with variable tuning whose point of suspension can be made to turn proportionally to the acceleration of the earthquake. When the pendulum is tuned for the period T, it can be shown that its maximum amplitude yields the value of A. By varying the tuning it is then possible to plot the spectrum $A(T)$ point by point. The main advantages of this type of analyzer are its low cost, its simplicity of operation, and the fact that it takes an average of eight hours to plot one spectrum curve. The use of a torsion pendulum at the Bureau of Reclamation to evaluate earthquake stresses was mentioned by J. L. Savage, Hon. M. Am. Soc. C. E., in 1939.[9]

The following earthquakes have been analyzed (their spectrum curves are plotted in fractions of gravity g against period in seconds):

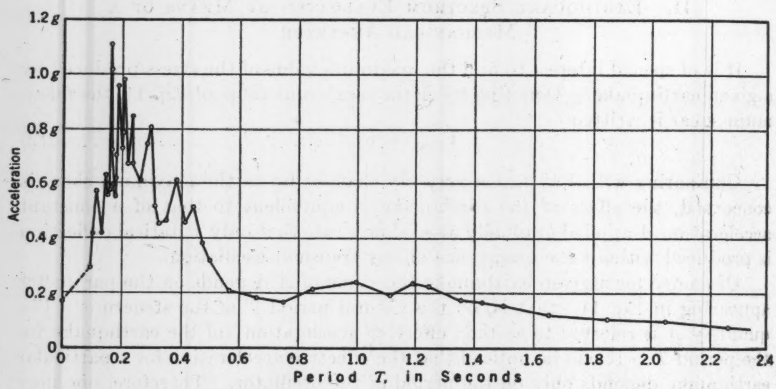

FIG. 3.—SPECTRUM OF EAST-WEST HORIZONTAL ACCELERATION OF THE EARTHQUAKE OF HELENA, MONT., OCTOBER 31, 1935

(A) Helena, Mont. (October 31, 1935) a horizontal east-west acceleration. The spectrum in Fig. 3 shows that a peak value of 1.05 g occurs for $T = 0.16$ sec. The maximum recorded acceleration of the earthquake is 0.16 g; and the amplification due to resonance is $\frac{1.05}{0.16} = 6.5$ times this value.

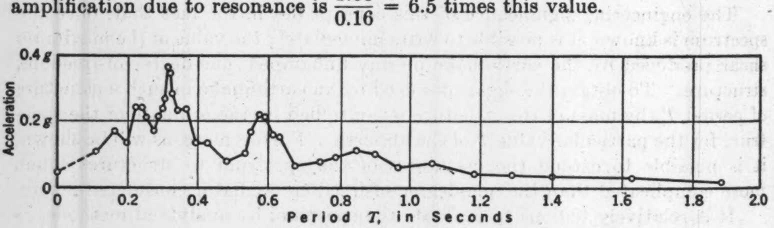

FIG. 4.—SPECTRUM OF THE NORTH-EAST HORIZONTAL ACCELERATION OF THE EARTHQUAKE OF FERNDALE, CALIF., FEBRUARY 6, 1937

(B) Ferndale, Calif. (February 6, 1937) a horizontal northeast acceleration. The spectrum in Fig. 4 shows that this is a minor earthquake. Its maximum intensity is 0.039 g, and the amplification is 9.5.

---

[9] "Earthquake Studies for Pit River Bridge," by J. L. Savage, *Civil Engineering*, August, 1939, pp. 470–472.

(*C*) Ferndale (September 11, 1938) horizontal accelerations in both northeast and southeast directions. The maximum recorded intensity is 0.17 g in the northeast direction and the amplification is 6. Both spectrums are found to be analogous to (*A*).

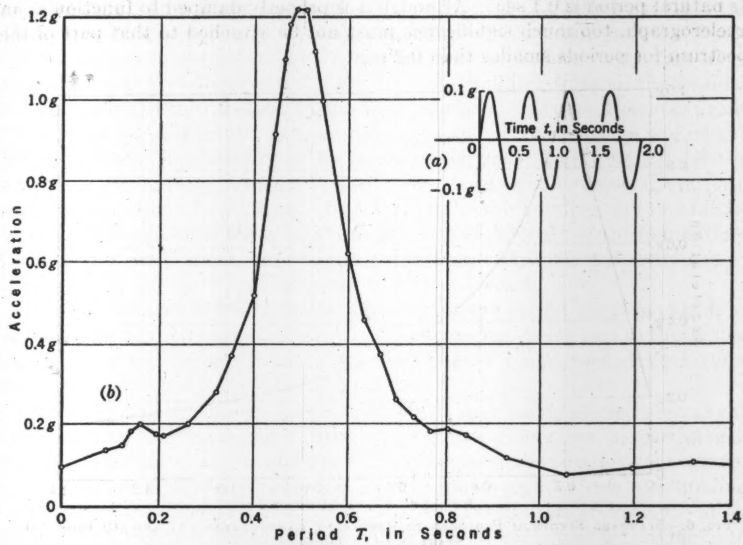

FIG. 5.—SPECTRUM OF AN ARTIFICIAL EARTHQUAKE CHARACTERIZED BY A SINUSOIDAL ACCELERATION

(*D*) A sinusoidal earthquake (Fig. 5(*a*)) of intensity 0.1 g and a duration of four cycles of 0.5 sec each was analyzed. Its spectrum is plotted in Fig. 5(*b*). The peak value of 1.23 g obtained is in good agreement with the theoretical value 1.25 g.

III.—SPECTRUM RELATED TO DESIGN AND ACTUAL BEHAVIOR OF STRUCTURES

It is apparent that, from the viewpoint of the designer, the individual sharp peaks in the spectrums are unimportant since their frequencies do not seem to be characteristic constants of the location as found by a comparison of the two Ferndale earthquakes (*B*) and (*C*) (see section II). The envelope of the spectrum, or better still, the envelope of a collection of spectrum curves obtained at the same location, constitutes the basic information for design purposes. A simple spectrum such as that plotted in Fig. 6 might well be taken to represent the Helena and Ferndale earthquakes ((*A*) and (*C*), section II). For $T > 0.2$ sec, the curve is chosen as the hyperbola

$$A = \frac{0.2\,g}{T} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

which emphasizes in quantitative form the fact that buildings of longer periods undergo smaller stresses. In general, therefore, high buildings will be less vulnerable to earthquakes than the smaller structures with shorter periods. The accelerograms from which these spectrum curves have been derived were recorded with the instrument designed by the U. S. Coast and Geodetic Survey. Its natural period is 0.1 sec. Although it is properly damped to function as an accelerograph, too much significance must not be attached to that part of the spectrum for periods smaller than 0.2 sec.

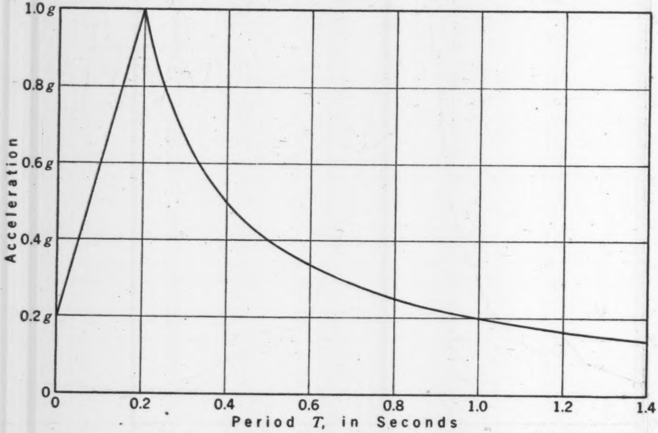

FIG. 6.—STANDARD SPECTRUM PROPOSED TO REPRESENT EARTHQUAKES (A) AND (C) FROM THE STANDPOINT OF DESIGN

Before proceeding any further it is important to give more careful consideration to the possible engineering interpretation of the foregoing results. The spectrums for earthquakes (A) and (C) indicate that an undamped structure with a period of approximately 0.2 sec would undergo a horizontal shear equal to its own weight. From observation of the effects of earthquakes this value seems rather high, but it must be remembered that it constitutes an upper limit and that actually a number of stress-reducing factors enter into play.

One of these factors, of course, is the damping influence of the structure. The magnitude of this damping effect must depend very much on the nature of the structure and the amplitude of the stresses. In fact, the damping observed with the aid of building vibrators or during minor earthquakes may very well be small, but one must be prepared to discover that in a strong earthquake the damping is considerably greater. When the amplitude of the stress reaches the yield point in some part of a structure, plastic deformation and friction will produce a high degree of energy dissipation. Assuming, for instance, that this type of damping occurs as soon as the spectrum ordinate is greater than 0.2 g, any further increase of stress by resonance will be strongly counteracted. That structural damping is an important factor agrees with the conclusion of studies by Professor White.[10]

---

[10] "Friction in Buildings: Its Magnitude and Its Importance in Limiting Earthquake Stresses," by M. P. White, *Bulletin*, Seismological Soc. of America, Vol. 31, No. 2. April, 1941, pp. 93–99.

Another stress reduction is that due to the influence of the foundation. This influence is threefold. When oscillations are set up in a building, strains are produced in the foundation and energy is dissipated, by internal friction in the soil. This effect depends on looseness, shear strength, internal damping, etc. A second cause of stress reduction is the radiation of elastic waves into the soil because of the motion of the building. This phenomenon was the object of a theoretical investigation by K. Sezawa and K. Kanai.[11] By this effect the energy of the oscillations is drained from the building through the foundation and radiated into the soil in the form of elastic waves. The magnitude of this effect depends on the size and natural period of the structure and on the elastic constants and density of the surrounding soil. The elasticity of the foundation will have an influence on the stresses because it increases the natural period of vibration of buildings. In other words, the building will not follow the horizontal motion of the ground but, due to the elasticity of the foundation, it will tend to rock about its center of percussion. This effect is examined in more detail in section V, and is shown to be considerable.

Finally, it must be noted that a variation of the period with amplitude is very effective against resonance effect. The stress limitation due to this factor can be important especially in strong earthquakes when large deformations and local failures occur.

From the choppy aspect of the spectrum it may be concluded that slight differences in building periods may cause great differences in earthquake stresses. This may very well be one of the reasons for the paradoxical observation that the destructiveness of an earthquake varies greatly from one building to another at the same location. The differences are not as great as the spectrums would indicate, however, but this could be explained by taking into account the influence of the damping.

IV.—Effect of an Earthquake on a Structure with Many Degrees of Freedom

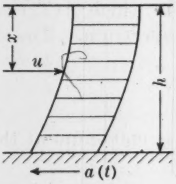

Fig. 7

The fact has been established that a number of modes of oscillation are excited by the earthquake, each of which contributes to the stress.[4, 5] It can be shown that each mode behaves like a system with a single degree of freedom and that the concept of spectrum is applicable to each mode separately. This will be demonstrated briefly by a simple example. Consider a building of height *h*, total mass *m*, and total rigidity *k*, both *m* and *k* being uniformly distributed (Fig. 7). The building is assumed to behave like a shear beam such that a unit horizontal displacement at the roof is produced by a force *k*. The shearing oscillations of the building obey the equation

$$h\,k\,\frac{\partial^2 u}{\partial x^2} + \frac{m}{h}\,a(t) = \frac{m}{h}\,\frac{\partial^2 u}{\partial t^2} \ldots\ldots\ldots\ldots\ldots\ldots (14)$$

in which u is the displacement relative to the ground at a distance x from the roof, and $a(t)$ is the horizontal acceleration of the ground, taken positive in a direction opposite to u. Write the acceleration $a(t)$ as a Fourier series in x

---

[11] "Some New Problems of Forced Vibrations of a Structure," by K. Sezawa and K. Kanai, *Bulletin*, Earthquake Research Inst., Tokyo, Vol. XII, Pt. 4, December, 1934, p. 845; also "Decay in the Seismic Vibrations of a Simple or Tall Structure by Dissipation of Their Energy into the Ground," by K. Sezawa and K. Kanai, *ibid.*, Vol. XIII, Pt. 3, September, 1935, p 681.

$$a(t) = \frac{4}{\pi}\left(\cos\frac{\pi x}{2h} - \frac{1}{3}\cos\frac{3\pi x}{2h} + \frac{1}{5}\cos\frac{5\pi x}{2h}\cdots\right)a(t)\ldots\ldots(15a)$$

and the solution $u(x,t)$ of Eq. 14 in the same form:

$$u(x,t) = U_1(t)\cos\frac{\pi x}{2h} + U_2(t)\cos\frac{3\pi x}{2h} + U_3(t)\cos\frac{5\pi x}{h}\ldots\ldots(15b)$$

The quantities $U_1, U_2\cdots$, represent the unknown roof deflections of each mode. Substituting Eqs. 15 into the differential Eq. 14 and equating the coefficients of $\cos\frac{\pi x}{2h}$, $\cos\frac{3\pi x}{2h}$, etc., to zero, the following equations are found:

$$\left.\begin{aligned} m\frac{d^2U_1}{dt^2} + \frac{k\pi^2}{4}U_1 &= \frac{4}{\pi}m\,a(t) \\ m\frac{d^2U_2}{dt^2} + \frac{9k\pi^2}{4}U_2 &= -\frac{4}{3\pi}m\,a(t) \\ \cdots\cdots\cdots&\cdots\cdots\cdots \\ m\frac{d^2U_n}{dt^2} + \frac{(2n-1)^2k\pi^2}{4}U_n &= \pm\frac{4m}{(2n-1)\pi}a(t) \end{aligned}\right\}\ldots\ldots(16)$$

These equations are analogous to Eq. 6 for the structure with a single degree of freedom. According to Eq. 8*a* the roof deflection of the *n*th mode is:

$$U_n(t) = \frac{16m}{(2n-1)^3\pi^3k}\frac{2\pi}{T_n}\int_0^t a(\theta)\sin\frac{2\pi}{T_n}(t-\theta)\,d\theta\ldots\ldots(17a)$$

in which T_n is the period of the *n*th mode. The largest value attained during the earthquake for the roof deflection in the *n*th mode can be written:

$$U_n = \frac{16m}{(2n-1)^3\pi^3k}A(T_n)\ldots\ldots\ldots\ldots\ldots\ldots(17b)$$

in which $A(T_n)$ is the ordinate at $T = T_n$ of the aforementioned acceleration spectrum. The shear stress

$$V = hk\frac{\partial u}{\partial x}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(18a)$$

is maximum at the base, $h = x$; hence the maximum shear in the *n*th mode is

$$V_n = \frac{8}{(2n-1)^2\pi^2}m\,A(T_n)\ldots\ldots\ldots\ldots\ldots(18b)$$

Denoting by V_g the stress which would be produced by a statical horizontal acceleration equal to gravity

$$V_n = C_n\frac{A(T_n)}{g}V_g\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(18c)$$

in which

$$C_n = \frac{8}{(2\,n-1)^2\,\pi^2} \tag{19}$$

The expression $\frac{A}{g}\,V_g$ represents the shear that would occur in a structure of one degree of freedom with the same mass and period as the particular mode considered. The factor C_n may be called an "effectiveness factor" because it represents the extent to which this shear appears in each mode of the structure with distributed mass and rigidity. A more direct method of calculating these factors is available. Assume that some restraining mechanism is used so that the building can only deflect in its fundamental mode, and apply a horizontal statical acceleration g. The deflection will be found by the energy principle. The external work, W, done by the inertia forces applied gradually is:

$$W = \frac{1}{2}\,\frac{m\,g\,U_1}{h}\int_0^h \cos\frac{\pi\,x}{2\,h}\,dx \tag{20}$$

The elastic potential energy E_p in this deformation is more conveniently evaluated as the kinetic energy in the fundamental mode of vibration; hence:

$$E_p = \frac{1}{2}\,\frac{m}{h}\left(\frac{2\,\pi}{T_1}\right)^2 U^2_1\int_0^h \cos^2\frac{\pi\,x}{2\,h}\,dx \tag{21}$$

Equating expressions 20 and 21 gives

$$U_1 = \frac{16}{\pi^3}\,\frac{m\,g}{k} \tag{22a}$$

and the shear

$$V_1 = \frac{8}{\pi^2}\,m\,g = \frac{8}{\pi^2}\,V_g \tag{22b}$$

The factor $C_1 = \frac{8}{\pi^2}$ appears in this expression, and coincides, for $n = 1$, with the value (19) already found by the more elaborate previous method. The same method is applicable to the higher modes.

The values of the coefficients for the three first excited modes are: $C_1 = 0.810$; $C_2 = 0.0900$; and $C_3 = 0.0324$. Similarly coefficients can be found for all kinds of structures provided the natural modes of vibration are known. In the earlier work[4, 5] the effectiveness factors were computed for a building with an elastic first story. Some of these values are given in Table 1 for different values of the elasticity ratio $\frac{k_1}{k}$. The rigidity k_1 of the first story is

TABLE 1.—CONSTANTS C FOR VARIOUS ELASTICITY RATIOS

$\frac{k_1}{k}$	C_1	C_2	C_3
0	1	0	0
0.556	0.993	0.0295	0.00436
2.50	0.947	0.0712	0.0155
∞	0.810	0.0900	0.0324

the force necessary to produce a unit deflection of the second floor with respect to the ground, and k is the rigidity between the second floor and the roof. Note that for a rigid first story $\left(\frac{k_1}{k} = \infty\right)$ the coefficients are the same as the foregoing for a uniform building. These coefficients make possible a comparison of the relative importance of the various modes. In a building with uniform distribution of mass and rigidity, if 100% denotes the shear that would act in a structure with one degree of freedom under an earthquake of constant spectrum the fundamental mode of the uniform building picks up 81% of the shear, whereas the second and third modes pick up only 9% and 3% of the shear. Table 1 shows that the effect of an elastic story is to decrease, further, the importance of the higher modes relatively to the fundamental.

For the case of a cable or simple truss the maximum shear stress is also given by Eq. 18c with appropriate values of C_n. The bending moment in a truss is expressed as

$$M_n = B_n \frac{A}{g} (T_n)\, M_g \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

in which M_g denotes the maximum bending moment produced by a static horizontal force equal to gravity. The coefficients C_n and B_n depend on the type of structure and the particular mode of vibration. Values of these coefficients for a cable and a pin-ended uniform truss are given in Table 2. Only the symmetrical modes (n odd) are excited by the earthquake so that the coefficients for modes of even order are zero. It is seen that the importance of the higher modes for the bending moment tends to decrease more rapidly than for the shear. Comparing the importance of the various modes under the assumption that the spectrum follows a law of the hyperbolic type as in Eq. 13, the conclusion may be drawn that generally the higher modes are less dangerous than the fundamental. Exception must be made for the case of the shear in a flexural beam where it seems that each mode would carry about the same amount of shear. This is due to the fact that the effectiveness coefficients for shear in a mode of oscillation of the order n decreases as $1/n^2$ whereas the frequency of a flexural beam increases approximately as n^2. However, in practice, due to the increasing influence of damping in the higher modes, one would expect that their importance would always be less than that of the fundamental. The attention of the reader is called to the fact that the values of the effectiveness factors for the higher modes of a truss[2, 12] are erroneous.

TABLE 2.—COEFFICIENTS C_n AND B_n

Order of mode	$n = 1$	$n = 2$	$n = 3$
C_n for cable	0.810	0.090	0.032
C_n for pin-ended uniform truss	0.810	0.090	0.032
B_n for pin-ended uniform truss	1.03	0.038	0.008

Table 2 was applied to the evaluation of an upper limit for the stresses that would be produced by an earthquake of the Helena or Ferndale type in the San Francisco-Oakland Bay Bridge.[12] Conditions are found to be least favorable in the side-span truss which is treated as a pin-ended truss with a period of 3 sec. For this period the effective acceleration of the standard spectrum in Fig. 6 is $A = 0.066\,g$. The effectiveness factor B_1 for the bending moment in the fundamental mode is $B_1 = 1.03$; hence the bending moment is

---

[12] *Transactions*, Am. Soc. C. E., Vol. 106 (1941), p. 1385.

$$M_1 = 0.068\,M_g \qquad (24)$$

This means that the maximum bending moment during the earthquake is not greater than that due to a static horizontal acceleration of 6.8% gravity. From the foregoing values of the effectiveness factors it seems as if the stresses in structures with more than one degree of freedom are of the same order as those in a structure with a single degree of freedom. This is not always true, however, and a particularly dangerous condition may arise from assuming that it is.

Consider, for instance, that a mass m_1 is elastically restrained to the ground with a stiffness k_1, and that a much smaller mass m_2 is restrained to m_1 with a stiffness k_2 (Fig. 8). Denoting by u_1 and u_2 the horizontal displacement of m_1 and m_2, respectively, the equations for the amplitudes of the harmonic motion are

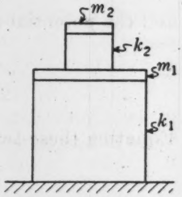

Fig. 8.—System with Two Degrees of Freedom, the Main Building and the Roof Structure

$$m_1 u_1 \omega^2 = k_1 u_1 + k_2 (u_1 - u_2) \qquad (25a)$$

and

$$m_2 u_2 \omega^2 = k_2 (u_2 - u_1) \qquad (25b)$$

in which ω is the circular frequency.

Assume that the small mass is "tuned" to the vibration of the large mass, by making

$$\frac{k_1 + k_2}{m_1} = \frac{k_2}{m_2} = \omega^2{}_1 \qquad (26)$$

Writing $\frac{\omega}{\omega_1} = \lambda$ the equations of motion become

$$(\lambda^2 - 1)\,u_1 + \frac{m_2}{m_1} u_2 = 0 \qquad (27a)$$

and

$$u_1 + (\lambda^2 - 1)\,u_2 = 0 \qquad (27b)$$

Hence, by elimination of u_1 and u_2,

$$\lambda^2 - 1 = \pm\sqrt{\frac{m_2}{m_1}} \qquad (28)$$

From Eqs. 27b and 28 the ratio of amplitudes is

$$\frac{u_2}{u_1} = \mp\sqrt{\frac{m_1}{m_2}} \qquad (29)$$

The lower sign refers to the fundamental mode. Now, in order to evaluate the effectiveness factor a restraint is assumed to force the structure to deflect in its fundamental mode while a static horizontal acceleration equal to gravity is applied.

The work done by the gravity force in deflecting the structure is

$$\frac{g}{2}(m_1 u_1 + m_2 u_2) = \frac{1}{2} m_1 g u_1 \left(1 + \sqrt{\frac{m_2}{m_1}}\right) \tag{30a}$$

and the potential energy is

$$\frac{\omega^2}{2}(m_1 u^2_1 + m_2 u^2_2) = \frac{m_1}{m_2} k_2 u^2_1 \left(1 - \sqrt{\frac{m_2}{m_1}}\right) \tag{30b}$$

Equating these two expressions yields

$$u_1 = \frac{1}{2} \, \frac{m_2 g \left(1 + \sqrt{\frac{m_2}{m_1}}\right)}{k_2 \left(1 - \sqrt{\frac{m_2}{m_1}}\right)} \tag{31a}$$

and the shear in the spring k_2 is

$$V_1 = k_2 (u_2 - u_1) = \frac{1}{2}\left(1 + \sqrt{\frac{m_1}{m_2}}\right) m_2 g \tag{31b}$$

Therefore the effectiveness factor is

$$C_1 = \frac{1}{2}\left(1 + \sqrt{\frac{m_1}{m_2}}\right) \tag{32}$$

It is seen that for small values of the mass ratio $\frac{m_2}{m_1}$ this factor becomes quite large. For instance, if this mass ratio is $\frac{1}{100}$, then $C_1 = 5.5$. If an earthquake acts on such a system the stress in the spring k_2 will be

$$V_1 = 5.5 \frac{A}{g}(T_1) V_g \tag{33}$$

or 5.5 times what it would be if the spring mass ($k_2 m_2$) were directly connected to the ground. Note that in Eq. 33, $V_g = m_2 g$ is the stress in the spring k_2 under a horizontal statical acceleration equal to gravity. This introduces an example in which the effectiveness factor C_n refers to a particular location in the structure. It is then possible to refer to the effectiveness factor "at a certain point" in the structure. The amplification effect revealed here belongs to a class of phenomena which might be designated as a "whip effect." Considered from the standpoint of wave propagation it is analogous to what happens in a whip, when a wave generated at the base is propagated to the tip. The wave may be considered as an energy lump moving from the heavy part of the whip to the lighter section at the tip. This produces at the tip a concentration of energy in a small mass and therefore gives rise to a high velocity. This effect is essentially associated with taper and explains many vibration failures in tapered beams, such as propeller tip failure or the fact that a tapered column receiving a blow at the base will fail at the tip. The case of two degrees of freedom, treated in the example, may well be considered as a simplified model of a tapered building. It points to the possibility of serious danger in roof structures and is in agreement with the observation of disproportionate damage in penthouses in the Long Beach earthquake of March, 1933. The California Building Code takes this danger into consideration by raising the lateral gravity force for which the penthouse must be designed.

The case of a structure in which the mass and stiffness both vary linearly with distance from the top was investigated by Professors Martel and White.[6] The effectiveness factor C_1 for total shear at various heights is:

Distance, $\frac{x}{h}$, from the roof	C_1
0	1.60
0.2	1.55
0.5	1.33
0.8	0.97
1.0 (base)	0.693

It is seen that these coefficients also point to the existence of a "whip" effect.

V.—Influence of Foundation on Motion of Blocks

The foregoing mathematical developments are based on the tacit assumption that the effect of an earthquake is the same as that of a shaking table. As will be shown now there is strong theoretical evidence that this concept must be modified to take care of the influence of the foundation. The elastic properties of the structure cannot be dissociated entirely from those of the ground and both must be studied simultaneously in order to predict the dynamic properties of the system.

The problem is extremely complex because it involves a complete knowledge of the propagation and properties of the seismic waves in the strongly heterogeneous surface layers of the earth as well as their diffraction and reflection by objects built on the surface. The influence of the soil on the damping of oscillations in structures was also discussed in the foregoing. An immediate answer to such a complex problem cannot be expected. It is believed, however, that the simplified problem noted in this section throws revealing light on the nature of foundation effects.

The question investigated is that of the influence of ground elasticity on the rocking motion of a block. How resistant is the surrounding soil to the rocking displacement of a foundation? What are the factors influencing this rigidity? Can this effect have a practical influence on the action of earthquakes on buildings? The problems are simplified by neglecting the mass of the soil, the internal friction in the soil, and the radiation of elastic waves due to the rocking.

Assume that the coordinate axes xy lie on the surface of the soil. A load-distribution $p(x)$-function only, of the distance x, is applied to the surface on a strip infinitely long in the y-direction and extending from $x = -L$ to $x = +L$. The distribution is asymmetric with respect to the y-axis so that

$$p(-x) = -p(x) \qquad (34)$$

It can be shown from the theory of elasticity that the soil deflection $w(x)$ is given by

$$w(x) = \frac{2}{\pi}\frac{(1-\mu^2)}{E}\int_0^L p(\xi)\log_e\left|\frac{x+\xi}{x-\xi}\right| d\xi \qquad (35)$$

in which E is Young's modulus of the soil and μ its Poisson ratio. Substitute in Eq. 35 the pressure distribution

$$p(x) = \frac{\alpha\, x}{\sqrt{L^2 - x^2}} \qquad (36)$$

Then, the deflection is a straight line:

$$w = 2\,\alpha\frac{(1-\mu^2)}{E}x \qquad (37)$$

In other words, the assumed pressure distribution (Eq. 36) is that under a rigid slab of width 2 L rocking about the y-axis. The ratio between the elastic moment M of p about the axis and the slope $\frac{dw}{dx}$ is the elastic stiffness coefficient C_r for rocking motion

$$C_r = \frac{M}{\frac{dw}{dx}} = \frac{\pi}{4}\frac{E}{(1-\mu^2)}L^2 \qquad (38)$$

If a uniform pressure distribution equal to a constant p from $x = 0$ to $x = +L$ and $-p$ from $x = 0$ to $x = -L$ is applied, the deflection of the soil is

$$w = \frac{2}{\pi}\frac{(1-\mu^2)}{E}p\,L\left(\log_e\left|\frac{L+x}{L-x}\right| + \frac{x}{L}\log_e\left|\frac{L^2-x^2}{x^2}\right|\right) \qquad (39)$$

From this solution it is possible to derive, by superposition, the deflection due to uniform asymmetric load distribution extending from $x = \pm L$ to various distances from the axis. It is found that the average rocking stiffness is given by a formula similar to Eq. 38 except that the numerical coefficient is somewhat different from $\frac{\pi}{4}$. For instance, in the case in which the load extends from

$x = 1$ to $x = \frac{4}{5}L$ and $x = -1$ to $x = -\frac{4}{5}L$ the coefficient $\frac{\pi}{4}$ is replaced by $0.231\,\pi$. It may be concluded that Eq. 38 represents a reasonable approximation, independent of the load distribution.

Eq. 38 implies the knowledge of the elastic constants E and μ of the soil. These are obtainable from tests made by M. Ishimoto and K. Iida.[13] Samples from the underground of several regions within Tokyo, Japan, at depths to 60 ft, were made into the form of rectangular prisms and submitted to vibration tests. The average values of the Poisson ratio are found to be about $\mu = \frac{1}{3}$.

Some of the values found for Young's modulus are

Material	E, in lb per sq in.
Silty clay in natural state with 50% moisture	792
Same with 42% moisture	5,750
Loam	8,200

From measured velocities of waves in soils[14, 15] the following order of magnitudes may be derived:

Material	E, in lb per sq in.
Loose sand	4,000
Clay	6,000
Sandstone	100,000

D. D. Barkan[16] has experimented, under field conditions, with various foundations weighing as much as 30 tons and having various areas at the bottom as great as 90 sq ft. The foundation was tested dynamically for rocking oscillations and also statically for the rocking rigidity of the foundation slab on the soil. The results are in good agreement with Eq. 38. A length of 21 was taken to represent the size of the square foundation slab used in the test. The values of E derived from this test are

Material	E, in lb per sq in.
Loess	12,000
Water-soaked brown loam	5,000

The order of magnitude of these values is in satisfactory agreement with the aforementioned values cited from other sources.

It is now possible to derive the rocking period of oscillation of a block lying on the soil. The results established in the preceding sections have shown that the fundamental period of oscillation of a structure is one of the essential controlling factors in earthquake stresses. The rocking period of a block is

[16] "Field Investigations of the Theory of Vibrations of Massive Foundations Under Machines," by D. D. Barkan, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Vol. II, 1936, p. 285.

$$T = \frac{2\pi}{\sqrt{\frac{C_r}{m\,r^2} - \frac{g\,h}{r^2}}} \qquad (40)$$

in which C_r is the stiffness of the foundation according to Eq. 38, m the mass of the block, r the radius of gyration with respect to the rocking axis, and h the height of the center of gravity above the ground. The term $\frac{g\,h}{r^2}$ represents the destabilizing influence of gravity. The case in which

$$\frac{C_r}{m\,r^2} = \frac{g\,h}{r^2} \qquad (41)$$

corresponds to statical instability when the tipping moment due to gravity is equal to the restoring moment of the soil. Usually the term $\frac{g\,h}{r^2}$ may be neglected and if the weight $m\,g$ is written as $m\,g = 2\,p_s\,L$ the period becomes

$$T = 9.5\sqrt{\frac{p_s}{E}\frac{r^2}{g\,L}} \qquad (42)$$

The pressure p_s is an average load on the foundation due to the weight of the structure. Consider the case of hard clay, and use for p_s the bearing capacity given by the Boston Building Code—$p_s = 84$ lb per sq in. According to the aforecited data, a reasonable value for hard clay seems to be $E = 15{,}000$ lb per sq in. The periods given in Table 3 are then obtained. With these values of the periods the spectrum may be used to evaluate earthquake stresses as explained previously herein.

TABLE 3.—VALUES OF THE PERIOD T, IN SECONDS

$2\,L$ (ft)	VALUES OF r, IN FEET			
	5	10	50	100
5	0.39	0.78	3.9	7.8
10	0.28	0.55	2.8	5.5
50	0.12	0.24	1.2	2.4

According to the standard spectrum in Fig. 6 the stresses are inversely proportional to the period of the structure. Since the soil can have a marked effect on the period it is to be expected that it exerts also a proportional influence on the destructiveness of the earthquake. Actually, of course, structures do not behave as rigid blocks, so that their period will be influenced by both the building and the foundation rigidity. The combined periods must be used in applying the spectrum curves to evaluate earthquake stresses. According to the data in Table 3 and Eq. 42 the slenderness of a structure has a considerable effect on its vulnerability to earthquakes. This probably bears some relation to the observed fact that columns and towers sometimes show paradoxical resistance with respect to neighboring structures.

CONCLUSIONS

Experimental and analytical methods of approach have been developed for the evaluation of earthquake stresses. An earthquake may be characterized by a certain function of period, called a spectrum, which is derived from the accelerogram by means of a mechanical analyzer. By using the spectrum an upper limit can be evaluated simply for the stresses produced in undamped structures of given dynamic properties. The stresses in each mode are shown to be derived quite simply from the value of the period and a coefficient dependent on the nature of the structure and referred to as the "effectiveness factor."

The comparison of stresses calculated by this method with observed destructiveness of an earthquake on a building seems to indicate that, at least for short periods, the values of the stresses obtained are considerably higher than could be expected. The possible effect of certain stress-reducing factors is discussed, such as internal damping in the soil and in the structure, the radiation of elastic waves, etc. The influence of these factors can become very large in certain cases.

Particular attention is given to the influence of the elasticity of the foundation and it is shown that considerable stress reduction occurs through the lengthening of the natural period due to the foundation. This is equivalent to stating that rigid slender structures will have a tendency to rock about the center of percussion because of the elastic yielding of the foundation.

Attention is directed to a phenomenon referred to as the "whip" effect which increases the destructiveness of earthquakes on penthouses and the tip of tapered columns and buildings.

Spectrum curves presented herein indicate that the effectiveness of an earthquake is inversely proportional (roughly) to the period, so that increasing the period means an increase in safety. Application of the methods developed in this paper should be helpful as a guide in extending safety rules and interpreting earthquake data.

A considerable field lies open for further research, especially as regards the stress-reducing factors discussed in section III. The influence of damping, for instance, could be taken into account by using a controllable amount of damping in the mechanical analyzer. This would yield a set of "damped response curves" which would give directly the effective acceleration for a building with given period and damping. In this terminology the spectrum would correspond to the undamped response curve. Further research should also be directed toward a better knowledge of the dynamics of the foundation, the interference of structures with one another, and the influence of agglomerations on the earthquake waves themselves.

ACKNOWLEDGMENT

The investigation summarized in section V was undertaken as part of a research program directed by Professor Martel and sponsored by the Los Angeles County Department of Buildings and Safety.

APPENDIX

NOTATION

The following letter symbols, adopted for use in this paper, conform essentially to Standard Letter Symbols for Mechanics, Structural Engineering, and Testing Materials, prepared by a Committee of the American Standards Association with Society representation and approved by the Association in 1932:[17]

A = effective acceleration giving the maximum value of shear through Eq. 12: $A(T)$ = acceleration spectrum;
a = linear acceleration:
  a_0 = constant horizontal acceleration;
  $a(t)$ = earthquake acceleration as a function of time (accelerogram curve);
  $a(\theta)$ = acceleration as a function of the variable of integration θ (Eq. 8*b*);
B_n = effectiveness factor for the bending moment in the *n*th mode (see Table 2 and Eq. 23); extent to which bending moment appears in each mode of the structure;
C_n = effectiveness factor for the shear in the *n*th mode (see Tables 1 and 2 and Eq. 18*c*); extent to which shear appears in each mode of the structure;
C_r = coefficient defining the stiffness of a foundation (Eq. 38);
E = modulus of elasticity: E_p = potential energy;
F = force;
g = gravity constant;
h = height;
k = spring constant; rigidity: k_1 = the rigidity between ground and second floor;
L = length;
M = bending moment:
  M_n = maximum bending moment in the *n*th mode of a truss (Eq. 23);
  M_g = maximum bending moment produced by a static horizontal force equal to gravity;
m = mass;
p = unit pressure; uniform pressure distribution:
  p_s = average load on a foundation due to the weight of the structure;
  $p(x)$ = pressure distribution under a rocking foundation at a distance x from the axis;
  $p(\xi)$ = pressure distribution with the variable of integration ξ in the place of x;

---

[17] ASA-Z10a-1932.

r = radius of gyration;

T = period of vibration; natural period of oscillation:

  $A(T)$ = acceleration spectrum;

  T_n = the period of the nth mode;

t = time;

U_n = $U_n(t)$ = largest value of roof deflection obtained during an earthquake for the nth mode, as a function of time;

u = displacement relative to the ground (u and v are taken positive to the right):

  u_0 = a constant deflection (Eq. 2);

  $u(x,t)$ = displacement at the instant t and distance x from the roof;

V = total shear in a structure:

  V_n = maximum shear in the nth mode of a cable or truss;

  V_g = maximum shear produced by a static horizontal force equal to gravity;

v = (see u);

W = work;

$w(x)$ = soil deflection;

x = distance from roof (Eq. 14); distance from rocking axis of foundation (Eq. 35);

α = (Eq. 36) a coefficient;

θ = variable of integration in Eqs. 8;

λ = ratio of natural frequency ω to ω_1 (Eq. 27*a*);

μ = Poisson's ratio;

ξ = variable of integration in place of x (Eq. 35);

ω = circular frequency: ω_1 = circular frequency defined by Eq. 26.

DISCUSSION

George R. Rich,[18] M. Am. Soc. C. E.—In modern seismic design, the use of arbitrary inertia loadings acting at the center of gravity of the structure has been superseded properly by the application of ground motions fairly representative of earthquakes to be expected at the site. Additional important economies and improved distribution of material still remain to be accomplished by increased recognition of the mitigating factors outlined by the author: First, the earthquake shock is transitory and the particular pattern required for resonance is generally repeated for only a few cycles; second, the effect of damping is controlling in cases approaching the resonant condition; and, third, a part of the seismic shock is dissipated in the propagation of elastic waves in the foundation due to the motion of the structure. Improved analytical technique is a distinct aid to progress along these lines.

Operational methods somewhat similar to the one used by the author in obtaining the seismic spectrum were evolved originally by Oliver Heaviside for studying the effect of transient electrical impulses and may be extended profitably, by means of the theory of functions of a complex variable,[19,20] in analyzing the effect of earthquake transients upon structures. These methods not only effect a great economy of time and labor by their directness and automatic elimination of integration constants, but they also afford a ready means of depicting the motion of the structure after the forced ground disturbance has been suppressed. In rigid structures with damping, this feature may be important since the response lags the transient driving impulse. Maximum stresses in such cases might occur after the ground motion ceases.

As an illustration, suppose it is desired to impress only *n* cycles of a sinusoidal ground acceleration upon Fig. 1 and to include the effect of damping. The basic differential equation is:

$$m \frac{d^2u}{dt^2} + \beta \frac{du}{dt} + k\,u = m\,a \qquad (43)$$

in which β is the coefficient of damping. For convenience, let $\beta/m = 2\,A$ and $k/m = B^2$. Then

$$\frac{d^2u}{dt^2} + 2\,A \frac{du}{dt} + B^2\,u = a \qquad (44)$$

The operational form for a sustained sinusoidal ground acceleration is $\frac{\omega\,p\,a_m}{p^2 + \omega^2}$, in which a_m is the maximum value of the ground acceleration (0.1 g in Fig. 5); ω is the angular velocity of the ground motion equal to $2\,\pi/T$, in which T is the period in seconds; and p, in the best modern terminology, represents the transform parameter in the Mellin inversion theorem.[21, 22] Heaviside called p the operator d/dt.

[19] "Complex Variable and Operational Calculus," by N. W. McLachlan, Cambridge Univ. Press, 1939.

[20] "Operational Methods in Mathematical Physics," by Harold Jeffreys, Cambridge Tract No. 23, Cambridge Univ. Press, 2d Ed., 1931.

The ground acceleration is suppressed after n cycles by incorporating the shift[23] operator e^{-q} (in which, to simplify typography, $q = 2\,n\,\pi\,p/\omega$), so that the operational form for the right-hand side of the differential equation becomes $(1 - e^{-q})\,\dfrac{\omega\,p\,a_m}{p^2 + \omega^2}$. From the basic differential equation, the operational form of u is:

$$u \supset \frac{(1 - e^{-q})\,\omega\,p\,a_m}{(p^2 + \omega^2)\,(p^2 + 2\,A\,p + B^2)} \ldots\ldots\ldots\ldots\ldots (45)$$

For the case of interest in seismic design, the zeros of $(p^2 + 2\,A\,p + B^2)$ are complex numbers, so, for convenience, let $\phi^2 = B^2 - A^2$; and then placing $i = \sqrt{-1}$:

$$u \supset \frac{(1 - e^{-q})\,\omega\,p\,a_m}{(p + i\,\omega)\,(p - i\,\omega)\,(p + A - i\,\phi)\,(p + A + i\,\phi)} \ldots\ldots (46)$$

By the Mellin inversion theorem:

$$u = \frac{\omega\,a_m}{2\,\pi\,i}\int_{c-i\infty}^{c+i\infty} \frac{(e^{zt} - e^{zv})\,dz}{(z + i\,\omega)\,(z - i\,\omega)\,(z + A - i\,\phi)\,(z + A + i\,\phi)} \ldots (47)$$

or

$$u = \frac{\omega\,a_m}{2\,\pi\,i}\left[\int_{c-i\infty}^{c+i\infty} \frac{e^{zt}\,dz}{(z + i\,\omega)\,(z - i\,\omega)\,(z + A - i\,\phi)\,(z + A + i\,\phi)}\right.$$

$$\left. - \int_{c-i\infty}^{c+i\infty} \frac{e^{zv}\,dz}{(z + i\,\omega)\,(z - i\,\omega)\,(z + A - i\,\phi)\,(z + A + i\,\phi)}\right] \ldots (48)$$

in which, to simplify typography, $v = t - \dfrac{2\,n\,\pi}{\omega}$.

Since the only singularities of the integrand are simple poles $z = -\,i\,\omega$; $+\,i\,\omega$; $-\,A + i\,\phi$; $-\,A - i\,\phi$; integration along the standard Bromwich contour is equivalent to $2\,\pi\,i$ times the summation of the residues[24, 25, 26, 27] at the poles. The value of the first integral inside the brackets, Eq. 48, accordingly is:

$$u = a_m\left\{\frac{(B^2 - \omega^2)\sin\omega\,t - 2\,A\,\omega\cos\omega\,t}{(B^2 - \omega^2)^2 + (2\,A\,\omega)^2}\right.$$

$$\left. + \frac{(2\,A^2 - B^2 + \omega^2)\,\omega\sin\phi\,t + 2\,A\,\phi\,\omega\cos\phi\,t}{e^{At}\,\phi\,[(B^2 - \omega^2)^2 + (2\,A\,\omega)^2]}\right\} \ldots\ldots\ldots (49)$$

for $t > 0$ and $< 2\,n\,\pi/\omega$.

[23] "Complex Variable and Operational Calculus," by N. W. McLachlan, Cambridge Univ. Press, 1939, p. 129.

[24] "Complex Variable and Operational Calculus," by N. W. McLachlan, Cambridge Univ. Press, 1939, p. 53.

[25] "Functions of a Complex Variable," by E. T. Copson, Oxford Univ. Press, 1935 ,p. 117.

[26] "The Taylor Series," by P. Dienes, Oxford Univ. Press, 1931, p. 233.

[27] "The Theory of Functions," by E. C. Titchmarsh, Oxford Univ. Press, 2d Ed., 1939.

The value of u for all times between $t = 0$ and $t = 2\,n\,\pi/\omega$ is to be taken from this expression only, which, it will be noted, correctly gives $u = 0$ and $du/dt = 0$ when $t = 0$.

The values of u after suppression of the ground acceleration are given by the sum of both integrals within the brackets, Eq. 48:

$$u = a_m \left\{ \frac{(2\,A^2 - B^2 + \omega^2)\,\omega \sin \phi\, t + 2\,A\,\phi\,\omega \cos \phi\, t}{e^{A\,t}\,\phi\,[(B^2 - \omega^2)^2 + (2\,A\,\omega)^2]} \right.$$

$$\left. - \frac{(2\,A^2 - B^2 + \omega^2)\,\omega \sin \left[\phi\left(t - \frac{2\,n\,\pi}{\omega}\right)\right] + 2\,A\,\phi\,\omega \cos \left[\phi\left(t - \frac{2\,n\,\pi}{\omega}\right)\right]}{e^{A\,v}\,\phi\,[(B^2 - \omega^2)^2 + (2\,A\,\omega)\,]} \right\} \quad (50)$$

for $t > 2\,n\,\pi/\omega$.

The use of this combined value is valid only for times greater than $t = 2\,n\,\pi/\omega$. Emphasis is placed upon this important characteristic of the use of shift operators in general.[28] The time is referred to the time of quiescence as an origin, but the use of the sum of the two integrals is correct only subsequent to $t = 2\,n\,\pi/\omega$.

The operational method is not limited to impressing sinusoidal transients. Operational forms for a wide variety of impulses are available.[29] Among these may be noted as possible components of actual accelerograms the diminishing Bessel wave $p/\sqrt{p^2 + 1}$ and the Morse dash or hammer blow $(1 - e^{-p\tau})$. Operational methods also make it possible to combine these various elementary impulse forms; for example, the Bessel wave represented by the foregoing operator may be impressed immediately following a sine wave of $n + 1/4$ cycles, fairly approximating the characteristic graph observed on typical accelerograms. In synthesizing ground motions in this manner, care should be taken to incorporate in the operational derivation the fact that the system is quiescent at the start of the first impulse, but in motion at the start of the second component impulse.

N. J. HOFF,[30] ESQ.—Predicting the stresses in buildings due to earthquakes is probably the most complicated problem a civil engineer may encounter. In problems of stresses caused by static or steady dynamic loads the use of refined mathematical methods may be required to obtain a rigorous solution, but, as a rule, an approximate answer satisfactory for practical design purposes can be obtained by the use of only elementary mathematics. Such is not the case with earthquake vibrations. Without an involved mathematical analysis not even the order of magnitude of earthquake stresses can be predicted.

The first part of this paper presents Professor Biot's earlier complicated theoretical contributions to the solution of problems of earthquake stresses in a form easily understandable to structural engineers. The explanation of the concept of the "earthquake spectrum" is of special interest since it may lead eventually to a simple routine engineering approach to this involved problem.

[29] *Ibid.*, p. 155.

[30] Asst. Prof., Aeronautical Eng., Polytechnic Inst. of Brooklyn, Brooklyn, N. Y.

Advantages of the mechanical analyzer in Fig. 2 are obvious for the determination of the "spectrum." It may be of interest to compare this device to the "shaking table" used in the experiments conducted in the Earthquake and Vibration Laboratory of Stanford University, Stanford University, Calif., where the writer had the opportunity to work under the direction of Professor Jacobsen. This shaking table is mounted on balls and is actuated by a cam and follower arrangement in such a way that its motion is a replica of the recorded horizontal motion of the ground during an earthquake. On the shaking table is mounted a single-degree-of-freedom vibrating system, the forced vibration of which is recorded. The spectrums of several earthquakes were established with the aid of the shaking table.

The general appearance of the spectrums obtained at Stanford University is very much the same as that of the curves in Professor Biot's paper. The maximum oscillator acceleration, however, was found to be about 0.5 g in the Stanford tests whereas Fig. 3 of the paper shows a peak value of about 1.1 g. It is suggested that the reason for this discrepancy is the intrinsically higher frictional damping of the shaking table. Systematic investigations at Stanford University showed that small changes in the friction have little effect upon the motion of the oscillator if the friction is comparatively high, but the effect is very marked when the friction is low. Of course, even the accelerations found at Stanford are much higher than those experienced by actual buildings during the same earthquake. This must be so, since the great majority of buildings designed to withstand a horizontal acceleration of 0.1 g only was not damaged. The reason may be found in the internal friction of the buildings and in the effects of the foundation as explained by Professor Biot. Nevertheless, a mechanical analyzer with low friction has theoretical advantages and a damping can always be applied to it if required.

A great advantage of Professor Biot's mechanical analyzer is its ease of operation. This is due mainly to the fact that it makes direct use of the accelerogram of the earthquake. For the investigations on the shaking table the accelerogram is integrated twice and the displacement curve so obtained is used for constructing the cam. The numerical integration is very laborious as is evident to all who ever saw an earthquake accelerogram. For this reason, Professor Martel of the California Institute of Technology suggested the use of the accelerogram for the construction of the cam. Such a procedure, however, was not found practicable since it would require a cam of prohibitively large diameter.

In the investigation of the vibrations of buildings with distributed mass and elasticity, Professor Biot made the tacit assumption that the maximum shear in the building is the greatest of the maximum shears of the different natural frequencies. In the Stanford tests it was found that in many cases the time of the occurrence of the maximum shear was approximately the same for single-degree-of-freedom models of different natural frequencies when subjected to the same ground motion. If this holds true for buildings of many degrees of freedom, the cumulative effect may cause a maximum shear greater than indicated by the spectrum. Furthermore, it is even conceivable that in such a case the maximum shear would occur somewhere else than at the base of the building. It is thought that this problem may merit some further consideration.

The calculations relative to the "whip effect" and the influence of the foundation are of great importance to practical design. It is desirable that the investigation of these problems be continued with a view to establishing a reliable and easily applicable procedure of calculation such as was achieved in the simpler cases with the aid of the concept of the earthquake spectrum. It is hoped that, in due season, Professor Biot again will be able to devote some of his time to problems of earthquake stresses in buildings.

MERIT P. WHITE,[31] ASSOC. M. AM. SOC. C. E.—Professor Biot's paper is probably one of the most significant of those which have appeared in the field of engineering seismology. Although many of the ideas presented are not new, nevertheless the fact that this is the first published attempt to present a complete picture of the earthquake problem makes it important.

As in nearly every other branch of engineering, there are two possible ways to attack the problem of earthquake resistant design. One of these represents the empirical, trial-and-error school of thought which, in general, is responsible for the present design methods. Actually, this approach can give, and has given, excellent results, partly on account of what must be called "engineering intuition." Nevertheless, the writer prefers the other approach, which may be characterized as the rational approach, which attempts to isolate and to understand the significance of the different factors involved in a problem. The rational method may be based on experiment, or on a combination of experiment and theory. Certainly, Professor Biot's paper is representative of this approach.

Mechanical Analysis of Accelerograms.—The use of the mechanical analyzer described by the author certainly will result in a saving of time when compared with the arithmetical solution for the response of an oscillator to an earthquake. However, the writer believes that the difference is not always as great as the author implies. In 1938 a comparatively rapid tabular method for solving the equation of motion was developed at the California Institute of Technology.[6] This method has the advantage that the effects of various amounts of damping can be found with little additional labor. Of course, a further advantage is the fact that such a method requires no mechanical equipment. So far as the writer knows, the first use of the mechanical analyzer for finding oscillator response to an earthquake motion was by Frank Neumann of the U. S. Coast and Geodetic Survey in 1936. In this work the earthquake displacement curve, obtained by double integration of an accelerogram, was used to govern the motion of a torsional pendulum. In 1939, Ralph E. Byrne, Jr., Jun. Am. Soc.

---

[31] Palmer Physical Laboratory, Princeton Univ., Princeton, N. J.

C. E., and the writer suggested a method by which an accelerogram might be used directly to actuate a mechanical analyzer.[32] This is the principle of the author's analyzer.

Peaks Appearing in Spectrum Curve.—The physical explanation for the peaks that always appear in an earthquake spectrum is a matter of importance. If these peaks truly represent characteristics of the basic earthquake motion, then, as suggested by the author, they may account for some of the paradoxical occurrences in earthquakes. However, to the writer, a more satisfying explanation is one suggested by Hugo Benioff of the California Institute of Technology; namely, that the peaks appearing in an earthquake spectrum are due to the influence of the motion of the building housing the recorder on the record made by the recorder. To test this hypothesis, extensive forced vibration tests, in which a shaking machine was used, were made by the U. S. Coast and Geodetic Survey with the assistance of Mr. Byrne and the writer in the summer of 1938.[6] It was found: (*a*) That there was definite correlation between the natural building periods and the periods of spectrum peaks for the earthquake records made by recorders in the buildings in question; and (*b*) that forced oscillation of a building gave measurable motion not only in the basement of the structure, where recording instruments may be located, but over a surrounding area, 1,000 ft or more in extent. Hence, spectrum peaks may even be caused by neighboring structures. The building coupling effect, in which a faint but regular motion is superimposed on the basic earth motion, might not be in evidence on the seismogram, but on account of its regularity it would have a large effect on the spectrum.

Change of Building Period with Amplitude.—The author states that a change of building period with amplitude of motion is effective against resonance effect. This is generally true, although it is conceivable that the opposite may occur—that is, an oscillator which is slightly off resonance may acquire enough amplitude to cause a period change, putting it in better resonance. However, if the spectrum peaks are not characteristic of the basic earth motion, true resonance cannot exist, and a small change of building period will have no particular importance.

Effect of Foundation Yielding and of Non-Uniformity of Mass Distribution or Stiffness of Building.—The general case, in which the structure is not uniform and rests on a yielding foundation (but has vertical planes of symmetry, or near symmetry), can be treated quite simply as follows: To determine the maximum shearing force at the base of the structure, the frequencies and shapes of the lower modes of vibration and the distribution of weight along the height of the building are needed. No other information regarding the foundation or the characteristics of the structure is required (damping is neglected). The natural frequencies of any building are found easily by the use of vibration meters or by comparison with similar structures in similar locations. The mode shapes (usually only the fundamental is really important) ordinarily can be assumed with sufficient accuracy. The distribution of weight is easily found, of course.

[32] "Model Studies of the Vibrations of Structures During Earthquakes," by Merit P. White and Ralph E. Byrne, Jr., *Bulletin*, Seismological Soc. of America, Vol. 29, No. 2, April, 1939, pp. 327–332.

As was stated by the author, the total response will be the sum of the responses of the various modes, the fundamental mode predominating. Each mode will be excited in much the same way as is a simple oscillator of the same period.

Letting $Y_n(x)$ be the shape, T_n the period, and V_n the maximum shear at the base of the building, all for the nth mode of vibration, and $\rho(x)$ the mass per unit height of structure at the height x, it can be shown that

$$V_n = A(T_n) \frac{\left[\int_0^h Y_n(x)\,\rho(x)\,dx\right]^2}{\int_0^h Y^2{}_n(x)\,\rho(x)\,dx} = m\,A(T_n)\,R_n \ldots\ldots\ldots (51)$$

in which

$$R_n = \frac{1}{m}\,\frac{\left[\int_0^h Y_n(x)\,\rho(x)\,dx\right]^2}{\int_0^h Y^2{}_n(x)\,\rho(x)\,dx} \ldots\ldots\ldots\ldots\ldots\ldots (52)$$

In Eq. 51, $A(T_n)$ is the ordinate of the author's acceleration spectrum at $T = T_n$, h is the height of structure, and m is the total mass of the building. Thus, R_n is the multiplying factor that gives the ratio between the maximum shear at the base, caused by the nth mode, and the maximum shear in a simple oscillator of equal mass and the same period. (Note that only the shape of $Y_n(x)$ is significant, and that the scale assumed has no effect.) Eq. 51 can be shown to reduce to Eq. 18*b* of the paper for the particular case in which weight distribution and stiffness are both constant.

Now, for the fundamental mode, consider the importance of foundation yielding and of mode shape on the numerical value of the multiplying ratio R, defined by Eq. 52, as demonstrated for the following cases:

(1) Weight concentrated at a point (the simple oscillator). Ratio $R = 1.0$.

(2) Structure has uniform stiffness and weight distribution; base is rigid. Ratio $R_1 = 0.81$.

(3) Weight is uniformly distributed, and the fundamental mode is linear as in Fig. 9 (this might represent a very stiff structure on a yielding base, a structure having a particular variation of stiffness, or one in which bending and shearing deflections are about equally important). Ratio $R_1 = 0.75$.

(4) Weight uniformly distributed; fundamental mode is parabolic as in Fig. 10 (this is approximately the shape for bending deflection). Ratio $R_1 = 0.555$.

The effect of non-uniform distribution of weight will be similar to the effect of variation of mode shape. It appears that for the fundamental mode the maximum shear generally will vary between the value corresponding to the ordinate of the acceleration spectrum and about one half this amount. It can be shown that the sum of all the R_n-values for any symmetric structure must equal unity. Hence, R_1 cannot exceed unity, which is its value in the case of the simple oscillator. Also, the smaller the value of R_1, the greater must be the remaining R-values and the more important will be the shears due to the higher modes.

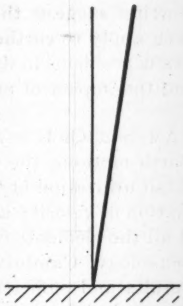

FIG. 9.—LINEAR FUNDAMENTAL MODE

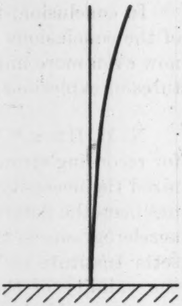

FIG. 10.—PARABOLIC FUNDAMENTAL MODE

Relative Importance of the Fundamental and the Higher Modes.—The relative importance of the fundamental and the higher modes in a particular case will depend on: (*a*) At what point of the structure shear is determined; (*b*) the values of the different R_n-values of the structure; (*c*) the periods and shapes of the different modes; and (*d*) the shape of the acceleration spectrum.

As an illustration, consider a uniform structure on a rigid base. Then, $R_1 = 0.81$; $R_2 = 0.09$; $R_3 = 0.032$ (from Table 1); and $T_1 : T_2 : T_3 = 1 : \frac{1}{3} : \frac{1}{5}$. Assume that the spectrum shape is given by Eq. 13—that is, $A(T) = \frac{0.2\,g}{T}$. Then, $A_1 : A_2 : A_3 = 1 : 3 : 5$; and, at the base of a uniform structure, $V_1 : V_2 : V_3 = 0.81 : 0.27 : 0.16$.

Variation of Shear with Elevation.—Away from the base, the situation will be somewhat different from that at the base. For example, using the same spectrum as before, at a point one third down from the roof of a uniform building, the maximum shears due to the different modes are in the ratios $V'_1 : V'_2 : V'_3 = 0.40 : 0.27 : 0.08$. Here, the second mode shear is about two thirds as great as the fundamental shear.

The effective acceleration for a section of a building, or the ratio of the maximum shear at that point to the total mass above it, is not a constant, as is generally implied in building codes, but increases with elevation. Considering only the fundamental mode of a uniform building, the following effectiveness factors are found:

Relative distance $\frac{x}{h}$ below the roof	Effectiveness factor C'_1
0.0	1.275
0.2	1.255
0.5	1.145
0.8	0.965
1.0	0.810

Thus, the maximum acceleration at the roof of a uniform building, caused by its fundamental mode, is 1.275 times the maximum acceleration of a simple oscillator of the same period, and is $\frac{1.275}{0.81} = 1.57$ times the effective acceleration for the entire structure. This is the "whip effect" mentioned by the author. It is present in any flexible structure.

In conclusion, the writer suggests that much of the information and many of the conclusions which apply to earthquakes are also applicable to what are now even more important problems in dynamics—namely, the effects on structures of explosions, and the impact of projectiles.

N. H. HECK,[33] M. AM. SOC. C. E.—With the development of the program for recording strong earth motions, the Coast and Geodetic Survey has recognized the necessity of full utilization of the results. Its principal contribution has been the determination of velocity and displacement (oscillatory) from the accelerograms so that all the elements of motion are known. The Massachusetts Institute of Technology, Cambridge, Mass., has cooperated in testing the validity of the results and sufficiency of their accuracy for engineering purposes. Little has been done in the application of the results to engineering design. However, the collection of engineering information after a destructive earthquake and the determination of building periods and the periods of other structures, in some cases at intervals during construction, constitute a close relation with practical engineering problems.

For these reasons the paper and previously reported work of Mr. Biot have been especially welcome. Its essential feature is the use of the earthquake spectrum obtained from strong-motion accelerograms with his mechanical analyzer. The spectrum gives a direct measurement of the maximum shear in a building due to a given earthquake. One thing is disconcerting—the high maxima in the relatively weak Ferndale (Calif.) shocks. The motions at El Centro, Calif., due to the Imperial Valley earthquake of March 18, 1940, were considerably greater than had been expected and accordingly one might expect very high maximum values of the spectrum for a major earthquake.

Mr. Biot states that there are a number of reasons for believing that the internal damping of structures is appreciable, and that since he has used an undamped pendulum, high resonance values are due in some measure to lack of damping in the torsion pendulum. The analysis obviously should be extended to include some forms of damped pendulums.

In general, it has been held that the tower type of building has special advantages as an earthquake resistant type, but the whip effect on the upper stories cannot be neglected.

The effect of the building on the ground is important from the viewpoint of the Coast and Geodetic Survey strong-motion program. By engineering advice all but about six of the sites adopted were in buildings and the instruments installed in the basements probably are affected by the motion of the building in the earthquake. The fact that the building at El Centro is small has enhanced the value of the conclusions from the El Centro record.

The paper emphasizes the importance of the determinations which have been made of the vibration periods of buildings, since without this knowledge the maximum stress cannot be determined for a given building. The conclusion that change of period damps out resonance is undoubtedly correct, but further investigation of the possibility that prolonged resonance in special cases may result in serious damage is needed.

---

[33] Asst. to the Director, U. S. Coast and Geodetic Survey, Washington, D. C.

The paper is stimulating to thought and opens up important lines of investigation. Interest in the subject has not been diverted by the war effort, but few persons are left to work on the problems. Interest in high-acceleration high-frequency vibrations has greatly increased but progress should be made in the entire field of vibrations including the relatively low-frequency long-period vibrations characteristic of destructive earthquakes.

Frank Neumann,[34] **Affiliate Am. Soc. C. E.**—Equivalent acceleration spectrums, as well as those for velocity and displacement, open up a new and vitally important avenue of attack on the engineering aspects of the earthquake problem. The way now seems to be clear to furnish the engineer seismic data in a form that he can put to direct use. The development of spectrums by practical methods has been considered a seismological as well as an engineering problem, and workers in both fields have made important contributions toward current accomplishments.

An interesting feature of the "standardized" spectrum is that, if reduced to "equivalent maximum velocity," the curve will show a constant maximum velocity for all periods greater than 0.2 sec. This would seem to provide an "intensity factor" in standard units for any earthquake motion that has been thus analyzed. This factor, in the case of the Helena north-south component, is 2.4 times the maximum velocity of the ground motion; but the Helena "standardized" curve cannot, as Professor Biot infers,[35] be considered typical of all curves in view of the effect of epicentral distance, for one thing, on ground periods. A notable instance of this distance effect occurred in 1933 when an earthquake originating 183 miles from the San Jose (Calif.) Bank of America Building registered an acceleration, on the thirteenth floor, seven times greater than the recorded ground acceleration of 0.005 *g*. The approximate resonance period in this case was 1.6 sec. The need for families of spectrums is thus obvious if earthquake motions are to be adapted to standard patterns. It appears that, for any one earthquake, the acceleration spectrums at different epicentral distances may be restricted in magnitude to the limits of a spectrum obtained very close to the epicenter, barring all geological influences.

It is thought that the apparent multiplicity of periods in the short-period end of the spectrum may be due, in some measure at least, to difficulty in following the acceleration curve during the analyzer work with the necessary precision, especially since resonance is likely to occur between the motion of the torsion-head lever arm (which is manually operated) and the motion of the pendulum. In a similar operation in 1936[36] (to determine the equivalent response of a 5-sec pendulum with a torsion pendulum analyzer) the writer found that it required considerable skill to follow the east-west component of the Helena acceleration curve, moving with the equivalent of the middle speed used in Professor Biot's work, even though the curve was magnified seven times. It is believed that the use of acceleration curves expanded many times, as now used in integration processes in the Coast and Geodetic Survey, would work for greater precision at these critical periods. As to the general form of the spectrum, recent ground period studies[37] indicate that the period pattern changes somewhat with the orientation of the seismograph pendulums, a condition which may be expected to be reflected in the computed spectrums.

[35] "A Mechanical Analyzer for the Prediction of Earthquake Stresses," by M. A. Biot, *Bulletin*, Seismological Soc. of America, Vol. 31, No. 2, April, 1941, pp. 163–164.

[36] "A Mechanical Method of Analyzing Accelerograms," by Frank Neumann, *Proceedings*, Am. Geophysical Union, Washington, D. C., May 1 and 2, 1936; also "The Simple Torsion Pendulum as an Accelerogram Analyzer," by Frank Neumann, *Publications du Bureau Central Seismologique International*, Serie A: Travaux Scientifiques, Fascicule 15, 1937.

With reference to that part of the spectrum below 0.2 sec, the error of Coast and Geodetic Survey accelerometers very seldom exceeds 15% or 20% between 0.1 and 0.2 sec. An experiment is now (1942) under way to test the practicability of shortening accelerometer pendulum periods with a view to increasing the range (downward) for recording true acceleration, and increasing the general recording capacity by decreasing the sensitivity.

It is unfortunate that some of the most valuable acceleration records are difficult to read because of overlapping of curves and occasional overdevelopment of the photographic paper. Overdevelopment is sometimes necessary to bring out the faint records of light spots moving at higher speeds and through larger amplitudes than had been anticipated in the original recorder design. Although these records do not always offer the sharpness of detail and cleanliness which Professor Biot desired in his work, it is nevertheless a fact that only one record to date has been lost to the extent that the data are not available for engineering studies. Available records include two of the Long Beach (Calif.) earthquake of 1933 yielding maximum accelerations of 0.06 *g* and 0.21 *g*, and maximum displacements of 20 cm double amplitude; also one of the Imperial Valley earthquake with maximum acceleration of 0.35 *g* and double amplitude of 40 cm. Comparing these values with the maximum of 0.16 *g* and displacement of 6 cm involved in Professor Biot's Helena spectrum, some idea may be obtained of the magnitude of the spectrums to come. Moreover, in spite of the magnitude of the recorded motion in the case of the Imperial Valley earthquake, the damage at the recording point, El Centro,[38] was "confined to walls that were not reinforced or tied, and to projecting balconies." The amplitude to be expected in an earthquake of catastrophic proportions can only be conjectured.

Concerning the inference that the torsion pendulum is[39] "a less accurate but simpler analyzer" than the proposed electrical apparatus, there will always be a doubt in the writer's mind until actual experience with both types proves the point. Any lack of accuracy in torsion pendulum analyzers would seem to lie in the manner in which the variable acceleration is transferred to the torsion head of the pendulum rather than in the functioning of the pendulum itself; and again, with reference to the statement in Section II of the paper that "it takes an average of eight hours to plot one spectrum curve," engineers are likely to be misled on the magnitude of the task which future workers in this field will face, remembering that even records of intensity VIII earthquakes present a much more formidable problem in processing than one of the Helena type which does not represent an intensity greater than VI. The Helena instrument was mounted on a limestone foundation and not on valley fill where most of the damage occurred in the 1935 earthquake.

JACOB FELD,[40] M. AM. SOC. C. E.—In characteristic fashion the author prepares a complete and logical derivation of various factors concerning the effect of earthquake vibration on physical structures. The writer is chiefly interested in that section concerning the influence of the foundation on the motion of blocks. In the approach to a solution of that factor, Professor Biot makes the assumption that the soil characteristics do not change during the vibration. Based also upon the assumption that the soil displacements within the limits of the deformations or deflections resulting from the vibrations of the block do not exceed the elastic limit strain, he deduces a formula for the rocking motion of the block, as restrained by the resisting characteristics of the soil.

Practical experience with vibrating structures embedded in soil does not confirm the assumptions made. It is well known in construction practice that, when vibrating machinery such as air compressors are placed on concrete foundations embedded in soil that has been made very heavy to dampen vibrations and thereby reduce their transference to adjacent structures, there is a change in the damping effectiveness with time. The only explanation for the change must be an alteration of the characteristics of the soil. It seems that continuous vibration of this nature increases the density of the surrounding soil. In some instances the writer has noted that a definite gap develops between the faces of the embedded concrete foundation and the adjacent soil. In such instances the vibration transference is considerably reduced, suddenly appearing again when, due to rain or other causes, the gaps are filled in. In one contract the writer designed a support that was kept entirely free from the adjacent soil and was bedded on a layer of cork. A gap was maintained on the four sides of the supporting base over a period of three years, and measurements made of the transference of vibration showed a loss of at least 90% of the compressor vibration wave. The period of the compressor vibration was 0.25 sec. Measurements were made by a vibrograph instrument which reported both horizontal and vertical components on a celluloid sheet.

Investigations of the effect of earthquakes and similar vibrations on the lateral pressure of earth have been made by Nagaho Mononobe and Haruo Matsuo.[41] These men found that the pressure of earth against a vertical retaining wall increased quite suddenly to a maximum upon the application of a vibration similar to an earthquake. The amount of increase depended upon the severity of the shock; but in each case the total pressure was found to be maximum immediately upon the application of the vibration, with a slight decrease thereafter. However, the measured pressure after vibration was larger than that before vibration, and the only explanation seemed to be that the material changed in character. This was somewhat substantiated by a series of tests with more compact fills, which did not show as large an increase in pressure from vibration. It also was found that the pressure against rigid walls was increased to a larger extent than pressure against deformable walls. This again seems to indicate that the change in pressure was caused by a change in the characteristics of the fill. Incidentally, the author concludes that the maximum earth pressure under earthquake conditions can be calculated from the usual earth-pressure formula by the use of a density equal to the resultant acceleration obtained by graphic summation of the acceleration of gravity and the maximum seismic acceleration.

[41] "Experimental Investigation of Lateral Earth Pressure During Earthquakes," by Nagaho Mononobe and Haruo Matsuo, *Bulletin*, Earthquake Research Inst., Vol. X, 1932, Pt. 4.

GEORGE W. HOUSNER,[42] JUN. AM. SOC. C. E.—In so far as it treats the earthquake problem from the viewpoint of vibration theory, this paper should prove of interest, particularly to engineers working in regions of seismic activity. That the effect of an earthquake is dependent on the physical properties of structures has long been known, and it was early recognized that the period of vibration of a structure was a significant index of its properties. One of the first attempts to measure the intensity of strong-motion earthquakes was made by Robert Mallet (1810–1881), a famous British engineer who made important contributions to seismology. The method used by Mallet[43] was to set up a group of six cylindrical wood blocks of graduated heights. By observing which of the blocks were overturned, he hoped to be able to classify the destructiveness of the earthquake. This wood-block approach has continued to interest engineers to the present time, but the rocking motion of a block is so complex that it has not been possible to draw any conclusions from the behavior of such a set of blocks.

A more satisfactory approach was taken by the late K. Suyehiro (1877–1932), noted Japanese engineer and one-time head of the Earthquake Research Institute of Japan. Suyehiro constructed a seismic vibration analyzer[44] to measure the intensity of earthquakes for different periods. This instrument[45] consisted of thirteen oscillators of different periods of vibration ranging from 0.22 to 1.81 sec. Such an instrument determines thirteen points on an earthquake spectrum such as that presented by the author. A defect of the instrument was the insufficient number of oscillators—that is, the gaps between the periods recorded were too large. Acting on a suggestion from Professor Martel, the San Francisco office of the U. S. Coast and Geodetic Survey constructed an instrument on this principle with a larger number of oscillators whose maximum displacement is recorded.

The strong-motion earthquake records furnished by the U. S. Coast and Geodetic Survey since 1932 have made it possible to compute the response of oscillators of different periods, thus greatly increasing the scope of this phase of seismological research. This computation can be done in several ways—namely, by numerical integration as was done by M. P. White[6] at the California Institute of Technology in Pasadena, and by F. Neumann[46] of the U. S. Coast and Geodetic Survey; by actuating a shaking table and measuring the response of oscillators as was done by Professor Jacobsen[7] at Stanford University in Stanford University, Calif.; or by utilizing the torsion pendulum as was done by Mr. Savage[9] at the Bureau of Reclamation and also by Professor Biot.

---

[42] U. S. Engr. Office, Los Angeles, Calif.

[43] "Dynamics of a System of Rigid Bodies," by E. J. Routh, Macmillan Co., 1913, p. 175.

[44] "A Seismic Vibration Analyzer," by K. Suyehiro, *Proceedings*, Imperial Academy II, 1926 (Tokyo), p. 286.

[45] A brief description of the instrument may be found in "Engineering Seismology: Notes on American Lectures," by K. Suyehiro, *Proceedings*, Am. Soc. C. E., May, 1932, Pt. 2.

A defect in this approach, as pointed out by the author, is that the computations are based on records of unknown accuracy. (A testing program to determine the accuracy of these strong-motion seismographs is being conducted at the Massachusetts Institute of Technology, in Cambridge, for the U. S. Coast and Geodetic Survey. The results of this investigation have not yet [June, 1942] been made public.) Any inaccuracy in the accelerogram will be reflected in the computed oscillator response curve or spectrum. It would be well for the author to call attention to the fact that the most reliable point on the computed spectrum is that for a period equal to zero. As stated by Professor Biot, the value of the computed oscillator response curve or spectrum is much increased by virtue of its application to structures more complex than a simple vibrating mass. This is particularly true since the vibration theory required has already been developed in the theory of acoustics. It is interesting to note that a building with shearing deformations is the mathematical analogue of a vibrating string, and the building with flexural deformations is the analogue of a tuning fork. This, then, is another instance in which the mathematics required by engineers has already been developed by physicists in the solution of analogous problems; even the analogue of the building with the flexible first story has been treated by them.

Since 1936, a program of earthquake research, sponsored by the Los Angeles County (California) Department of Building and Safety, has been conducted at the California Institute of Technology under the direction of Professor Martel. During this time spectra or oscillator response curves have been evaluated for the following earthquake records: Los Angeles Subway Terminal, March, 1933; Vernon, Calif., March, 1933; Los Angeles Subway Terminal, October, 1933; El Centro, Calif., December, 1934; Helena, Mont., October, 1935; and El Centro, May, 1940. In engineering terminology, these so-called spectra are in reality influence lines for maximum shear. The influence lines or spectra for the aforementioned earthquakes were found to be of two general types. These are illustrated in Fig. 11 where it will be noted that the records used were obtained from the same seismograph but for different earthquakes. The curve in Fig. 11(*a*) is similar to those presented by the author—that is, the ordinates decrease rapidly for increasing periods of vibration. In Fig. 11(*b*) this rapid decrease does not occur. It is seen that in this case the shear is not reduced, in general, appreciably by lengthening the period of vibration.

---

[46] Mr. Neumann also called attention to the use of the torsion pendulum for this problem in "Special Publication 201, Earthquake Investigations in California 1934–1935," Dept. of Commerce publication.

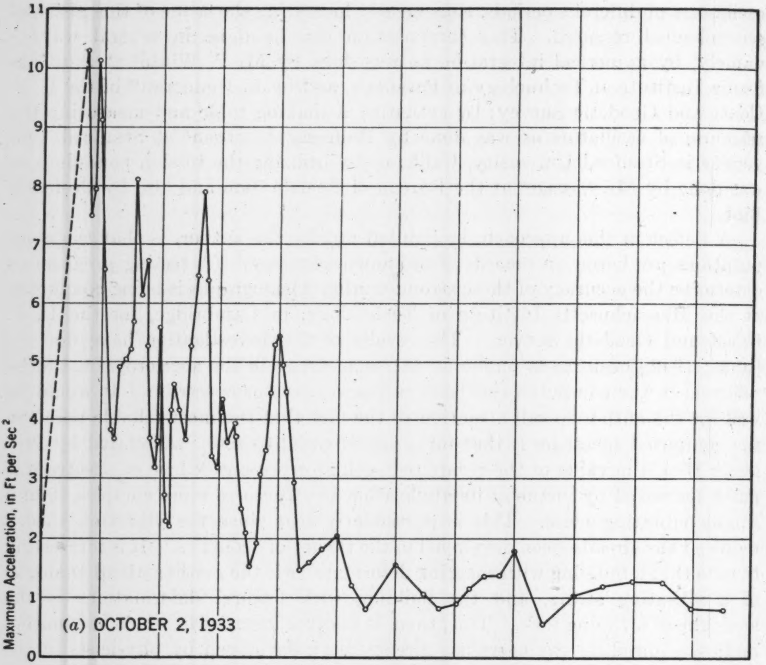

FIG. 11.—SPECTRA OF THE N 141° W COMPONENT OF THE LOS ANGELES SUBWAY TERMINAL RECORD

The problem of foundation yielding discussed by the author is a phenomenon well worth studying. It was first investigated by Suyehiro and Ishimoto[47] in 1926. These investigators constructed a special vibrograph and made measurements on the rocking oscillations of buildings.[45] Some results of their measurements are shown in Table 4. These were made on reinforced concrete buildings of very rigid construction. To compare values with the results of the author's analysis, it is necessary to recompute Table 3. In his calculations, Professor Biot has used the value $p_s = 84$ lb per sq in., apparently confusing allowable bearing pressure with actual building weight. On the basis of the dead load of typical buildings, it would be proper to take $p_s = 1.04$ lb per sq in. for each 12 ft of height. Recomputing on this basis gives the following values:

TABLE 4.—OBSERVED PERIODS OF VIBRATION

Laboratory	Stories	METERS			Ground	Period (sec)
		Length	Breadth	Height		
Aeronautics; main building	2[a]	56	15	11	Reclaimed	0.50
Mitsubishi Laboratory; main building	2[b]	60	14	10	Loam	0.35
Mitsubishi Laboratory; metallurgical room	1[a]	11	9	5	Loam	0.20

[a] No basement. [b] With basement.

Values of r (ft)	For $2L = 50$ ft, period T, in seconds, equals:
16	0.04
50	0.35
100	0.99

Only the structure 50 ft wide has been computed and the value $r = 16$ represents a height of 12 ft. As recomputed, it is seen that the calculated periods of the rocking oscillations are much shorter than the corresponding periods of the first modes of vibration would be. These computations would indicate that foundation yielding does not cause an appreciable stress reduction due to period lengthening.

A very extensive program of vibration measurements is reported in "Special Publication 201."[46] The periods of 212 buildings were measured and, of these, four showed evidence of possible foundation yielding. These four were low, rigid buildings on soft ground. The building vibrations (due to microseisms) measured by Suyehiro and Ishimoto[47] would also indicate that foundation yielding may be of importance for low, rigid structures on soft ground. It is of interest to note that Suyehiro concluded that the rocking oscillations were nonlinear since the period was dependent on the amplitude. The approach used by the author would not be applicable to nonlinear vibrations, although in itself nonlinearity would seem to be beneficial in reducing maximum shears.

---

[47] "Vibrations of Buildings," by K. Suyehiro and M. Ishimoto, *Proceedings*, Third Pan-Pacific Science Cong., Tokyo, 1926, p. 1482.

It appears that more experimental research is required to determine the fundamental characteristics of rocking oscillations of buildings.

HOMER M. HADLEY,[48] ASSOC. M. AM. SOC. C. E.—The gist of Professor Biot's scientific approach to the problem of earthquake resistant construction and to the improvement of codes appears to lie in his advocacy that recognition be given to the varying responses which different structures having different periods of vibration give to the same earthquake and, further, that recognition be given to varying types of foundations with their differing elastic properties and consequent differing effects upon structures built upon them. That such differences exist cannot be questioned, and it would seem entirely reasonable and logical to include consideration of these matters in design. When specific application is attempted, however, the engineer finds himself embarrassingly deficient in reliable data upon which to proceed. A sage saying which the writer heard years ago in Alaska was this: "Now, if we only had some ham, we'd have some nice ham and eggs for breakfast—if we only had some eggs." In short, for ham and eggs one must have both ham and eggs. Even so, for the application of the scientific method, the engineer must have reliable data for its basis. What is definitely known about earthquakes, about foundations, about the structures themselves?

One scientific fact about an earthquake always faithfully reported is the location of the epicenter. Not much else may be learned of it, but the location of the point on the earth's surface above the subterranean origin is readily determined. From the accumulation of these data engineers have come to know what regions are most subject to earthquakes, but beyond this there is no particular application of the knowledge made to earthquake resistant construction. Even the position of the epicenter is subject to question at times. At Long Beach, Calif., on March 10, 1933, the epicenter was first reported in the ocean bed some 15 miles off Newport Beach, Calif., where only slight damage occurred.[49] It seemed somewhat anomalous that the severe damage should have occurred at places much farther removed from the epicenter than Newport Beach. Later observations[50] led to the conclusion that there had been a series of epicenters at various points along the Inglewood, Calif., fault, there being a series of successive origins. Since these later epicenters were adjacent to the districts of severe damage, that much empirical confirmation of their existence is found.

As to the earthquakes themselves, the various records show certain common characteristics: An initial period of slight movement; then the period of severe, violent movement; and then the final period of diminishing, dying movement. As to their intensities, it is known that they vary widely. The accelerograms of the two Ferndale, Calif., earthquakes of February 6, 1937, and September 11, 1938,[2] are quite different. Who, on March 1, 1937, for instance, having seen the accelerogram and spectrum of the February 6, 1937, earthquake and of all preceding earthquakes at Ferndale, could have said that a more severe earthquake would occur on September 11, 1938, or, on any particular date, could have foretold what its accelerogram or spectrum would look like? Of necessity, such a prophet would have to employ "art based on observational facts and experience" rather than "science" as the basis of his prediction; so it is, with Ferndale, Calif., or with any Ferndale, large or small, upon this earth. Somewhere in his writings, Omori discussed the earthquake peculiarities of certain places and stated that there were individual characteristics and features to be observed; but except for a certain directional similarity there was nothing strikingly individualistic in these characteristics. Now, and probably for a long time in the future, engineers must be empirical in judging the earthquake to be assumed in design.

[48] Regional Structural Engr., Portland Cement Assn., Seattle, Wash.

[49] "Preliminary Report on the Long Beach Earthquake," by Harry O. Wood, *Bulletin*, Seismological Soc. of America, April, 1933.

[50] "The Determination of the Extent of Faulting with Application to the Long Beach Earthquake," by Hugo Benioff, *ibid.*, April, 1938.

As to the influence of the foundations on the motion of the structure, Professor Biot clearly states the complexity of the problem (see heading "V.—Influence of Foundation on Motion of Blocks"): "* * * it involves a complete knowledge of the propagation and properties of the seismic waves in the strongly heterogeneous surface layers of the earth as well as their diffraction and reflection by objects built on the surface." This undoubtedly is true and undoubtedly presents an obstacle to "science." It is stated that Eq. 38 implies the knowledge of the elastic constants E and μ of the soil but that "These are obtainable from tests made by M. Ishimoto and K. Iida.[13]" This is a happy solution of the difficulty: See what Messrs. Ishimoto and Iida give for these values. Nevertheless, it is to be noted in their quoted findings that a change of moisture content of silty clay from 42% to 50%—that is, a change of 8%—changes E from 792 lb per sq in. to 5,750 lb per sq in. Who is to know whether what he terms silty clay is the same as the silty clay defined by Messrs. Ishimoto and Iida, or what the moisture content of that silty clay may be when a foundation is subjected to an earthquake? Again, what manner of bedrock underlies the silty clay? Those who have driven the highways of Southern California and looked upon the confused, contorted, heterogeneous geologic structure revealed in cuts and excavations must feel mistrust and misgivings in whatever assumptions they may make as to the values of E and μ for scientific calculations.

As to the elastic properties of the structure that is being designed, it should be possible from measurements, past and future, of existing comparable structures to assume values fairly approximate to those that will develop. With values of T decided on, with what spectrum shall they then be used? Apparently there is only a very limited number in existence. Fig. 6 is a "standard" spectrum of two earthquakes only—that of Helena, Mont., on October 31, 1935, and the Ferndale earthquake of September 11, 1938. It shows that a natural period of 0.5 sec gives an acceleration of 0.4 g; a natural period of 1.0 sec gives an acceleration of 0.2 g. From the text one learns (see heading "III.—Spectrum Related to Design and Actual Behavior of Structures") that "The differences [in the behavior of buildings of different periods] are not as great as the spectrums would indicate." Apparently "Science" must be empirically modified, at times.

There is a further matter of engineering seismology to be considered, as well as the matter of intensity of stresses, which can be modified and altered by change of sections. This is the matter of greater deformations that accompany longer periods. The Marunouchi Building in Tokyo, Japan, the largest steel-frame building in that city, was under construction in 1922 when a considerable earthquake occurred. As a result of the distortions it sustained at that time, it was felt that the building needed stiffening. Consequently, a number of panels of diagonal bracing were introduced, extending from basement to roof, and these were covered with metal lath and plaster. When the great earthquake of September 1, 1923, occurred, these bracing panels were loaded terrifically at the outset and either stretched amazingly or ruptured. The natural period of the building then reverted to its original value. A number of different people who were in the building told the writer that they did not enjoy the experience. Partitions were cracked and shattered, marble trim in the corridors loosened and fell, and pendant lighting fixtures swung so violently that their reflectors knocked plaster off the ceilings. After it was all over the owners—perhaps not scientifically, yet empirically—rebuilt the exterior and interior walls and introduced bracing walls, for the definite purpose of making the building stiff—that is, giving it a low natural period of vibration. States a well-known advertisement: "Ask the man who owns one."

It must not be thought that making a building stiff will prevent an earthquake from being felt in it. On the contrary, whatever movement occurs at the foundations will be transmitted with little damping to the roof, and the building's contents will be shifted and perhaps thrown to the floor quite as if they stood upon the ground. On the other hand, after the earthquake has passed, a well-designed, rigid-type building will be found very satisfactory to all concerned. It may be added that all the comment made herein is limited to buildings of moderate height. As to skyscrapers, the writer has no knowledge other than that such buildings successfully passed through the San Francisco, Calif., earthquake of 1906.

Yet another aspect of the earthquake problem is the matter of occurrence. Fortunately, severe earthquakes are not frequent. It may well be questioned whether provision against them warrants highly elaborate and refined engineering design. The severe damages which have repeatedly occurred in the past have not resulted from failure to design for this or that value of shearing stresses in the structures involved but from completely ignoring earthquakes and all horizontal forces they entail. A definite observed deficiency in present design or proof that current practise is unwarrantedly too severe should constitute the basis of change and progress.

There is a widespread feeling among American engineers that some special virtue is imparted to the solution of highly complex, not to mention uncertain and unknowable, problems by going through mathematical processes in reaching a decision regarding them. They prefer to assume E and μ and all the various other variables that may be involved and to "figure" themselves to an answer rather than to accumulate empirical data and proceed simply and directly from them. There is much to be said for the mathematical process, but it contributes no more truth, no more science, than is put into its basic assumptions. The writer would conclude with the words of the late David A. Molitor, M. Am. Soc. C. E., used in the "Synopsis" of his paper "Wave Pressures on Sea-Walls and Breakwaters":[51] "Since all factors contributing to the solution of the problems herein considered are only approximately knowable, no theoretical approach was deemed advisable."

ROBERT E. GLOVER,[52] ESQ.—The author develops a method of using a torsion pendulum to determine the amount of resonance to be expected when a structure of known frequency is subjected to an earthquake. This ingenious procedure makes use of an accelerometer record obtained during the quake. A torsion pendulum operation based on the use of a displacement curve, derived by double integration of an accelerometer record, has been used by the writer for a similar purpose. A comparison of results obtained by the two methods is shown in Table 5, which is based on the East-West component of the Helena quake of October 31, 1935.

TABLE 5.—COMPARISON OF ACCELERATION RESULTS

Structure period (sec)	MAXIMUM ACCELERATION	
	Author's data[a]	Writer's data[b]
0.20	0.73 g	0.79 g
0.25	0.67 g	0.69 g
0.40	0.50 g	0.52 g
0.50	0.32 g	0.27 g
0.80	0.19 g	0.20 g
1.00	0.24 g	0.26 g
2.00	0.10 g	0.06 g

[a] Scaled from author's spectrum curve. [b] Based on an integration made by the U. S. Coast and Geodetic Survey.

The slight differences are probably due to the choice of values for the constants of integration used in computing the displacement curve. Since the accelerometer instruments are generally arranged to be put in motion by a starter, which responds to ground movement, a small part of the record near the beginning is lost, and there is, therefore, some room for exercise of judgment when the values of these constants must be selected. The results obtained by the two methods appear, however, to be in essential agreement.

M. A. BIOT,[53] ESQ.—Mr. Rich presents an application of the operational calculus to a simplified case. Since the response of structures to earthquakes is essentially of a transient character, it is natural to apply the methods specifically designed for the treatment of such phenomena. However, the difficulty in applying the Heaviside methods to the full extent is the non-analytical and random character of the seismogram. The simplified procedure derived by the writer avoids the computation of the actual motion and makes possible the direct evaluation of the maximum stress by the use of a standardized spectrum. However, the operational method can be used, as such, in combination with the spectrum, as a convenient way of deriving the effectiveness coefficients or any desired characteristic in the structure. This is especially true when the information needed is restricted to a particular variable or location in the structure. The operational method is also useful in investigating the response to simplified theoretical earthquakes, as shown in the examples set forth by Mr. Rich. The latter method acquires special value if a great number of cases are solved and if general principles are uncovered as to the comparative behavior of structures under standardized earthquakes. This approach might truly be called a mathematical, experimental method.

Professor Hoff mentions that the results obtained at Stanford University show the influence of the friction on the oscillator response. It is interesting to note the experimental fact that the response is very sensitive to changes in friction when the latter is small. It is probable that the differences in peak spectrum accelerations between the Stanford results and those of the writer are partly due to errors on the small-period components of the displacement cam. The question of the possible accumulation of the stresses in each mode by the simultaneous occurrence of their maximum values at a given point is well worth investigating. A conservative estimate can be made theoretically by adding the maximum values associated with each mode at various locations in the structure.

As stressed by Professor White, the idea of an automatic analyzer to avoid the numerical work in evaluating the response of a structure is not new. In the writer's earlier work in 1932, the mathematical groundwork was laid for showing the possibility of using the accelerogram directly without the process of evaluating the displacement. An electric model was suggested, of which the present torsional pendulum is the mechanical analogue. An electric model has been developed by Arthur C. Ruge, Assoc. M. Am. Soc. C. E., at the Massachusetts Institute of Technology in Cambridge, Mass.

Professor White raises an interesting and important point regarding the nature of the peaks in the spectrum. The writer called attention to the lack of correlation between the peaks in the two Ferndale earthquakes, (*B*) and (*C*), as supporting evidence that these peaks are not characteristic of the location. It is possible that some peaks might be characteristic of the location, or of a group of buildings, and that these would stand out particularly in earthquakes of small intensity where the effects of resonance seem to be more acute. More probably the hatched appearance of the spectrum is due to random transients superposed on a basic periodicity distribution. Professor White makes the statement that the whip effect, although less pronounced, also appears in structures that are not necessarily tapered. He also suggests the application of the present results to the effect of explosions and projectile impact on structures. The writer wishes to mention another possible application—determining the dynamic effect of wind on structures by introducing the spectrum of atmospheric turbulence.

Mr. Heck mentions the importance attached by the U. S. Coast and Geodetic Survey to the recording of high accelerations throughout the frequency range of earthquakes. The results already accomplished in this direction were an absolute prerequisite to the writer's work.

Mr. Neumann rightly warns against using a particular spectrum as a basis for final standardization. The writer uses the standardized Helena spectrum merely as an example. The spectrum peak seems to be correlated both in intensity and frequency to the distance of the epicenter. As stated by Mr. Neumann, it is probably true that the torsion pendulum analyzer is not necessarily less accurate than a more intricate electrical apparatus. The writer's statement on this matter was perhaps somewhat conservative, since the spectrum curves could be duplicated closely in spite of the rather crude design of the analyzer and the use of non-magnified seismographic records.

Mr. Feld recalls the change of damping characteristics with time in a vibrating soil. As stated by the writer, the treatment of a foundation is restricted to its elastic properties. The results are in good agreement with tests on actual foundations made by Mr. Barkan.[16] The magnitude of structure and soil damping is a factor left to future experimental investigation. The methods of the paper are applicable if it is desired to introduce the effect of this damping on the amplitudes of oscillation. However, in seeking to establish experimental data, it will be well to keep in mind that the vibrator itself can have a considerable effect on the properties of the soil.

The two spectra computed by Mr. Housner are interesting, in that they show the same general appearance as those obtained by the writer. The ratio of the spectrum peak to the maximum acceleration is also of the same order. The spectrum of the March 10, 1933, earthquake shows relatively high equivalent accelerations (of the order of 20% gravity) for the large periods. Mr. Housner presents an application of the writer's simplified formula for the rocking period of blocks. His results are based on a much lower bearing pressure than that used by the writer, and the rocking periods in this case are relatively short. Taking into account the possibility of the soil being considerably more spongy than assumed in the computations, it should be concluded that the effect of the foundation is important or not, depending on the magnitude of such factors as soil elasticity, foundation size, and height and rigidity of the building. It would seem, however, that in the case of towers or chimneys the rocking effect should be preponderant. In regard to the relations between acoustics and engineering seismology, a theorem[4,54] was originally developed by the writer which states that the energy accumulated by an oscillator depends only on the intensity of the impulse spectrum for the particular frequency. This theorem forms the basis of the present method and justifies the use of the spectrum.

Mr. Hadley's pimented discussion is enjoyable reading. His argument reduces to a confession of man's total ignorance of the subject, and the defeatist viewpoint that nothing can be done about it "Now, and probably for a long time in the future." Mr. Hadley, however, is anxious not to discredit the esoteric art of earthquake-proof design by contributing the following statement:

> "* * * after the earthquake has passed, a well-designed, rigid-type building will be found very satisfactory to all concerned. * * * As to skyscrapers, the writer has no knowledge other than that such buildings successfully passed through the San Francisco, Calif., earthquake of 1906."

---

[54] "Acoustic Spectrum of an Elastic Body Submitted to a Shock," by M. A. Biot, *Journal*, Acoustical Soc. of America, Vol. V, January, 1934, p. 207.

This, said the medieval doctor, is a sleeping potion; it makes you sleep because it contains a soporiferous virtue. It has been the writer's experience that a feeling of uneasiness usually develops when proselytes of the empirical method are brought in contact with symbols such as E and μ, even if they do not represent an essential part of the argument. This is entirely unfortunate and unjustified, as there is no fundamental conflict between empiricism and science. Mr. Hadley's objections might well have been raised three hundred years ago against the basic principles of Newtonian mechanics with their abstract and elusive concepts of force and mass.

Mr. Glover's results are in good agreement with those of the writer. They point to the comforting fact that satisfactory duplication of results is possible even when different methods and instruments are used.

In conclusion, the writer wishes to thank all those who have taken time to contribute to the present discussion for their constructive criticism.

HYDRODYNAMICS OF MODEL STORM SEWER INLETS APPLIED TO DESIGN

By G. S. Tapley,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Ralph W. Powell, and G. S. Tapley.

Synopsis

A technique is developed in this paper by which it is possible to apply experimental results from $\frac{3}{32}$-scale models of side-opening storm sewer inlets to the design of full-size prototypes. The method is applied to design in a single case, the development and presentation of design data for various other shapes, slopes, and dimensions being reserved for the future.

The phenomenon of flow into an inlet is characteristically gravitational in type, but the small depths of flow in the model suggest that the effect of viscosity is also important. Lateral deflection of the flow is an additional characteristic.

An equation was thus sought and obtained describing the portion of the flow entering the inlet in terms of Froude's and Reynolds' numbers and the moment of pressure and moment of momentum. The development of the form of the equation was facilitated by an analytical determination of boundary conditions corresponding to infinite and zero approach velocity.

Total differentiation yielded an expression in which Reynolds' number has an arbitrary value with respect to viscosity. A Reynolds' number of prototype magnitude, but with model velocity and linear dimension, was thus selected, the value of the coefficient of viscosity being computed. Integration by means of planimeter and the use of flow-distribution relationships yielded a result which represents flow in the model similar to flow in a prototype with regard to both Froude's and Reynolds' laws.

In developing the basic data important facts regarding flow distribution in the channel upstream from the inlet were discovered.

Notation.—The letter symbols in this paper are defined where they first appear and are assembled for reference in Appendix *B*.

Note.—Published in March, 1942, *Proceedings*.

[1] Junior Civ. Engr., Bureau of Eng., City of Los Angeles, Los Angeles, Calif.

I.—General

The action of prototypes can often be predicted from the observed operation of models together with the application of a single law of similarity, such as that of Froude or Reynolds. In other instances, such as in open-channel flow and ship-model work, no single law can be considered as being exclusively applicable.

The present case deals with the development of a technique for applying to the design of prototypes the experimental results from $\frac{3}{32}$-scale models of side-opening storm-sewer inlets of a type shown in Fig. 1. Flow approaching the inlets is turbulent and gravity is the principal force; Froude's law evidently is important. On the other hand, depths of flow in the model varied from about $\frac{1}{2}$ in. at the curb to film thickness at the outer edge of the stream; serious doubts would exist as to the validity of results in which the effect of Reynolds' number had been ignored. Flow approaching the inlets (except on streets with slopes flatter than about 0.005 ft per ft) is further characterized as being of the shooting type (velocity is greater than wave velocity). The flow, moreover, is wide in relation to depth and undergoes a lateral deflection in entering the inlet; a change of angular momentum is involved.

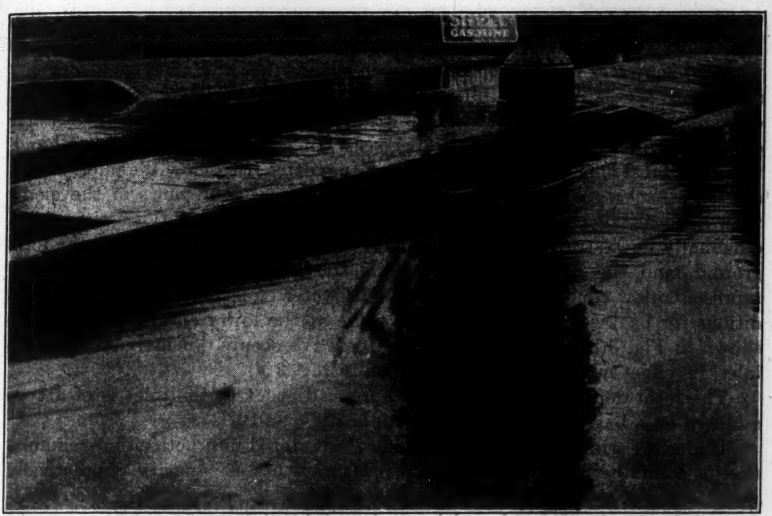
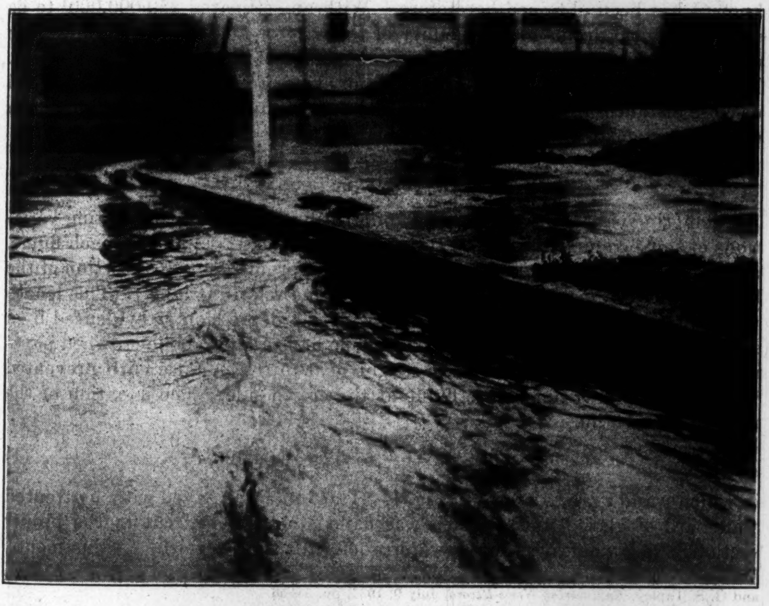
Fig. 1.—Storm-Sewer Inlet; 3/32-Scale

The development of technique described in this paper makes use only of the data necessary. Development of the remaining experimental data covering a range of shapes of depression, slopes of street, lengths of inlet, etc., remains for the future. The data utilized include only cases involving "free flow" at the lower end of the inlet. In this type of flow that portion of the water, if any,



(*a*) No Backwater Effects



(*b*) Considerable Backwater Effect

FIG. 2.—VIEWS OF FULL-SIZE INLETS SHOWING RELATIVE BACKWATER EFFECTS

which passes the lower end of the inlet has a velocity greater than wave velocity. Free flow is differentiated from "backwater effect," a condition that occurs when a backwater wave extends upstream of the lower end of the inlet. Fig. 2 shows two views of actual full-size inlets. The inlet in Fig. 2(*a*) has no local depression. There is a small gutter rise below the inlet, and no backwater effect. The flow, Q_t, is 0.9 cu ft per sec. In Fig. 2(*b*), on the other hand, there is a local depression and a 6-in. or 8-in. gutter rise below the inlet. Considerable backwater effect is evident. Fig. 3 shows four views of the model with various stages of backwater effect. For example, Fig. 3(*a*) is a view facing diagonally downstream toward the inlet. The approach flume is in the foreground, and the overflow notch is directly below the hammer. Fig. 3(*b*) represents flow conditions for a heavy backwater effect; and the limiting conditions for backwater effect, with the wave at the lower end of the inlet, are shown in Fig. 3(*c*). When the backwater wave occurs downstream from the inlet, its effect misses the inlet, as shown in Fig. 3(*d*).

The local depression or approach apron adjacent to the inlet is of a type adopted on a basis of experiments made in 1926 and 1927.[2]

Under the wide variety of conditions encountered in practice the accumulation of a number of isolated full-size measurements of capacity is practically worthless, and the advantage of a small model must be evident. The recentness of the development of model experimental technique, no doubt, accounts, in part, for the fact that no satisfactory solution of the problem (so far as is known) has been obtained heretofore. With an estimated $50,000,000[3] to be spent for storm drains in the vicinity of the City of Los Angeles, Calif., alone over a period of years, the economic importance of the problem is apparent. Moreover, a reexamination of the designs of existing installations probably will disclose instances in which the benefit of a part of investments already made in conduit systems is not being realized because of insufficient inlet capacity.

II.—APPARATUS AND TECHNIQUE

The principal apparatus consisted of a tilting framework (permitting variations of slope from zero to 10%) supporting a stilling tank, an approach flume, and the model depression and inlet. The plan, profile, and cross section of the latter are shown in Fig. 1. The approach flume was 10 ft long. (This length was sufficient to insure "developed" flow at the depression as evidenced by a series of tests.) It represented, to scale, one half of a parabolic-crowned pavement, 36 ft wide, having a crown height of 0.45 ft. A false curb prevented water from spilling out of the flume at the crown side. The equation of the model cross section is

$$(z - 1.688)^2 = -67.0\,(y - 0.0425) \qquad (1)$$

in which y and z are as shown in Fig. 1. The flume was paved with a patented wallboard of glazed finish, which was nailed to templates cut to the proper section. The whole was made waterproof with spar varnish. Adjustments,

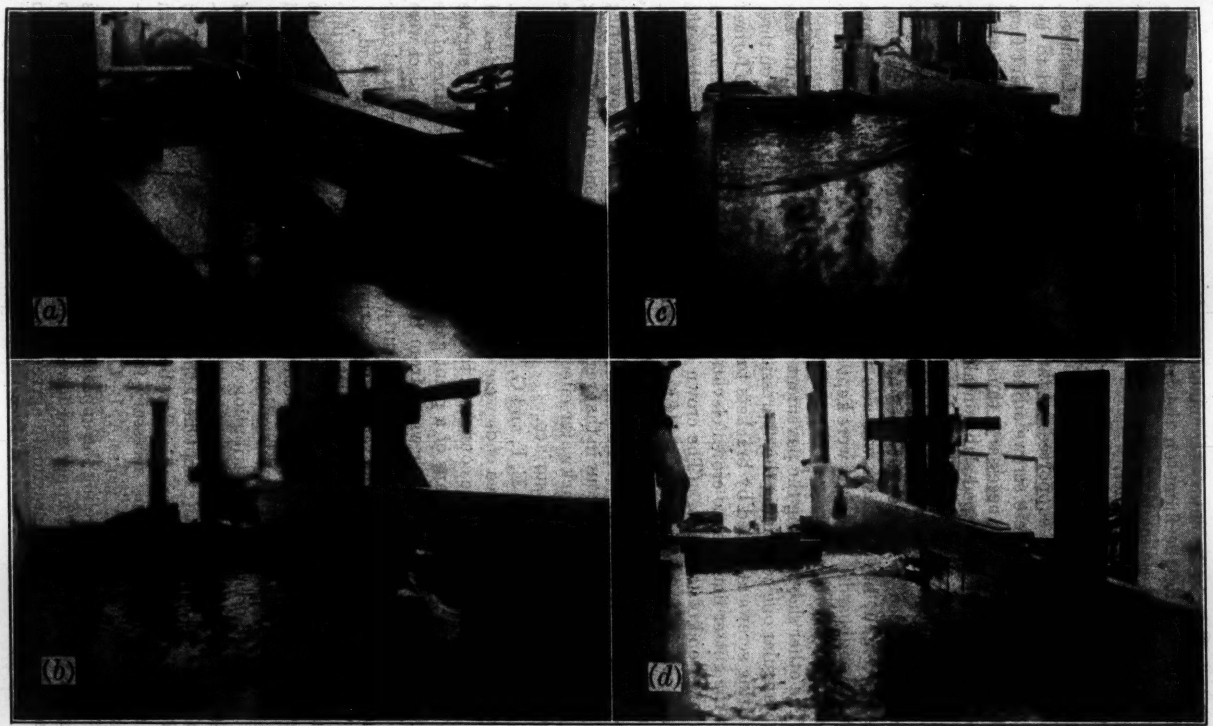

FIG. 3.—VIEWS OF MODEL INLET DEMONSTRATING BACKWATER EFFECTS

for warp and sag in the flume, were made by means of the adjusting screws and wedges supporting the flume on the framework. Local adjustments in the flume pavement were made by sandpapering high areas and filling in low ones with lacquer putty or lacquer.

The pavement of the lower end of the apparatus which contained the depression and inlet was formed from two concrete slabs. The outer, L-shaped, "permanent" slab was supported on three adjusting screws attached to the tilting framework. These screws adjusted the slab to a slope different from that of the flume, when necessary, thus varying the approach velocity in the experiments. The L-shaped slab contained the orifices for gages A, B, C, D, and E. The slab itself was formed to normal section throughout, the part having a surface above normal (Fig. 1) being built up with plaster of Paris. This was chipped off and rebuilt when models of different length were installed. Gage E, Fig. 1, in such cases was also moved to keep the standard distance from the endboard. All joints were kept smooth and watertight with a mixture of beeswax and resin.

The other slab forming the pavement of the lower end of the apparatus was a rectangular one containing the depression. This slab was supported on three adjusting screws attached by brackets to the L-slab. The slab was so formed that the gutter line rises to crown elevation at a point 12 in. downstream from the lower end of the inlet. (The crown elevation is 0.0113 ft higher than the normal elevation, which corresponds to an actual street with its curb face 8 in. normally and 4 in. at the center of the curb return.) For the present case—free flow—the contour of the pavement below the inlet has no effect on flow entering the inlet. Indeed, the contour in that region has little influence on flow entering the inlet even in case of backwater effect, the principal factor then being the elevation of the backwater surface.

Depth gages A, B, C, D, E, F, and G, Fig. 1, consisted of copper tubes, $\frac{3}{16}$ in. inside diameter, whose orifice ends were carefully set flush with the surface of the concrete, and which were connected to stilling wells where the water surface elevations were read by means of a point gage. The zero-flow readings of the gages were obtained by wiping water from the orifices until the menisci were perfectly flat, thus avoiding the effect of surface tension. Usually an average of at least three readings of the zero points during a day's run was obtained.

Total flow, Q_t, approaching the inlet was measured by means of an orifice meter calibrated by weighing. The excess flow, Q_e, or flow passing the inlet was measured by means of a 15° V-notch weir (also calibrated by weighing) and the inlet flow was found by subtraction.

Data on horizontal Q-distribution were obtained in a separate series of experiments by intercepting the flow in the normal channel between thin vertical vanes set 2 in. apart (except near the crown where the spacing was wider) and volumetrically measuring the flow between each pair of vanes over a given time interval. The depths necessary for computing velocities from the discharges were measured by gages A, B, C, and D, Fig. 1.

The procedure for leveling the apparatus was first to set the flume by means of grade marks near the upper and lower ends of the flume, then carefully to level the L-slab into approximate agreement with the flume. The next step was to adjust the lower end of the flume so that the joint was flush, ignoring the small departure from the lower flume marks. Adjustments in leveling the concrete were made until the difference in elevation between gages A and D, and between D and H, was correct to within 0.001 ft. This quantity was used as a criterion for acceptable accuracy throughout the model and lower end of the approach flume.

Readings of the gages were taken at time intervals of sufficient length to insure the existence of steady conditions, the weir being the controlling factor. Five minutes between weir readings was found to be a satisfactory interval. The maximum total flow in each set of readings was about 0.1 cu ft per sec, and the minimum about 0.02 cu ft per sec. The usual procedure was to turn on a flow of about 0.12 cu ft per sec for about 5 min, decrease the flow to about 0.10 cu ft per sec, wait for 2.5 min, locate the valley wave (a wave near the valley), read the orifice meter, read gages A, B, C, D, and E, and last, read the weir gage. Flow was then decreased in 6 or 8 stages at 5-min intervals to the minimum discharge. By this procedure the uneven effect of capillarity and surface tension on previously unwetted surfaces was avoided.

III.—Theory

For a fixed depth, a_0, and a known flow distribution in the channel upstream from the inlet, the ratio

$$K = \frac{\bar{z}\,P}{U} \qquad (2)$$

describes the flow within a distance z_i from the curb and represents a relationship between pressure and velocity patterns. In Eq. 2, $\bar{z}\,P$ is the moment of pressure, and U is the moment of momentum per second, or angular momentum per second, at the approach section, taking moments about the curb, corresponding to a filament of flow within a distance z_i from the curb.

The nature of K may be purely "distributional," or without regard to inlet flow; or it may be "gravitational," in which case the outer boundary of the filament of flow included coincides with the outer boundary of the inlet flow. In the latter case it must be evident that the value of K will depend upon the forces that act on the fluid as it passes from the approach section to the inlet lip. These forces may be described by means of a function of Froude's and Reynolds' numbers, and shape factors:

$$K = \phi\,(\bar{v}, h, \rho, g, \mu, a_0, d, t, c_s) \qquad (3a)$$

in which $\bar{v}\left(= \dfrac{G}{\rho\,Q}\right)$ is the average velocity of the water particles within a distance z_i from the curb; G = momentum per second; ρ = mass per cubic foot; and h is the fall of the water in passing from the approach section to the inlet lip. (The approach section was located 0.0625 ft upstream from the local depression, and thus a small part of the total fall represents fall in the approach channel. Depths were measured at a section 0.125 ft upstream from the depression. For cases in which the approach flume had a slope different from that of the model or the depth in the approach flume was greater than critical depth a small error in h is present.) Standard dimensional-analysis procedure now yields

$$K = \psi(\mathbf{F}, \mathbf{R}, A_0, D, T, C_s) \qquad (3b)$$

in which Froude's number is

$$\mathbf{F} = \frac{\bar{v}^2}{g\,h} \qquad (4a)$$

Reynolds' number:

$$\mathbf{R} = \frac{\bar{v}\,h}{\nu} \qquad (4b)$$

the approach-depth number:

$$A_0 = \frac{a_0}{h} \qquad (4c)$$

the depth-of-depression number:

$$D = \frac{d}{h} \qquad (4d)$$

the roughness number:

$$T = \frac{t}{h} \qquad (4e)$$

and

$$C_s = \frac{c_s}{h} \qquad (4f)$$

which is the number representing that part of h due to the normal slope of the model.

Variations in the ratio A_0 cause changes in the geometrical shape of the

approach-flow cross section. Analysis can best be made, therefore, by covering the desired range of values of the ratio in a series of steps, each step of which represents a constant value of A_0.

Moreover, c_s is constant so long as S, x, and l are constant. When, also, d is constant, h is constant, for,

$$h = a_0 + d + c_s \qquad (5)$$

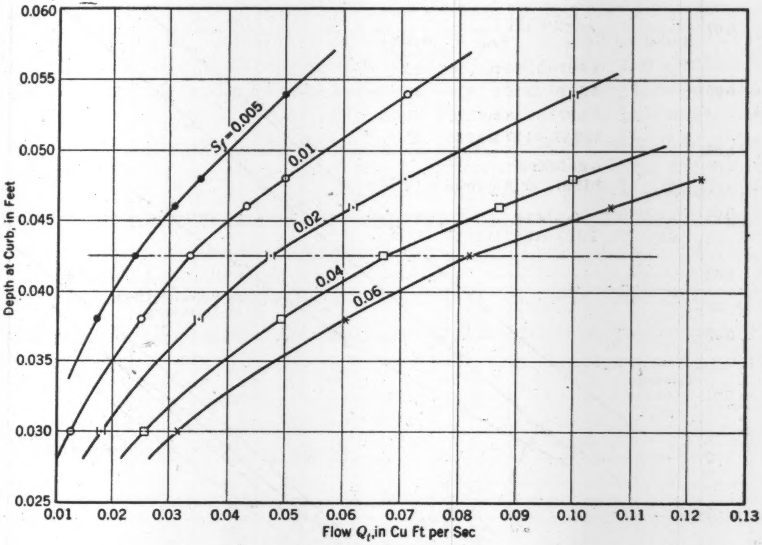

FIG. 4.—DEPTH AND DISCHARGE DATA

The magnitude, t, of the roughness protuberances was not varied in the model. (The results in this case apply to a prototype whose roughness particles are geometrically similar to those of the model. When, in the model, h is varied by varying d or a_0 the relative roughness varies although t itself is constant.) Under these conditions Eq. 3b reduces to

$$K = \theta(\mathbf{F}, \mathbf{R}) \qquad (6a)$$

or, in product form,

$$K = C_{AD}\, \alpha(\mathbf{F})\, \beta(\mathbf{R}) \qquad (6b)$$

This cannot be reduced further to simpler form, since (in the absence of varying ν or g) **F** and **R** vary simultaneously. The next step after preparing data in suitable form is to insert values in the equations and determine the forms of the functions, $\alpha(\mathbf{F})$ and $\beta(\mathbf{R})$.

IV.—PREPARING THE DATA

The experimental data required for an analysis of flow at the approach depth $a_0 = 0.0460$ ft are given in Table 1. Comparison can be made in the table between the average velocity $\bar{v}$ and the apparent average velocity $v'_t = \dfrac{\text{total discharge}}{\text{total area}}$.

Values of Q_t in the table were taken from Fig. 4 which represents the averaged result of a large number of depth, Q_t, observations. The averaging of depth-Q_t data was made necessary by the considerable dispersion of values. In the averaging process a cross slope of the water surface, which seemed to be systematic and to increase with S_f, the slope of the approach flume, was eliminated, and the resulting surface was made transversely level. The consistency of relationships described subsequently indicates acceptable accuracy of the resulting average. Slight discrepancies exist between tabular values of

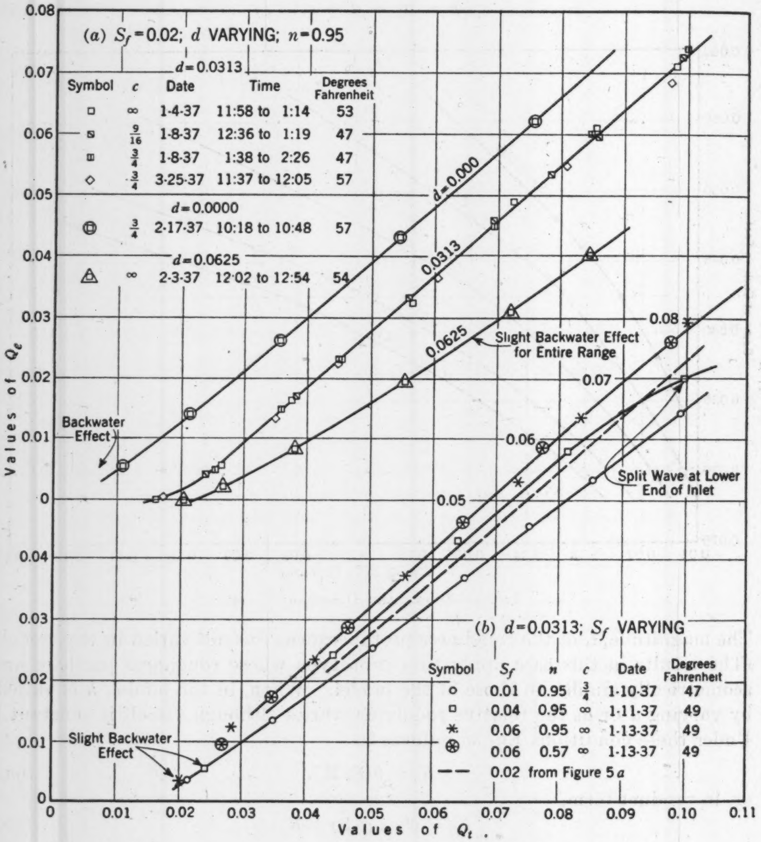

Fig. 5.—Experimental Flow Relationships

Q_t and those of Fig. 4 because of recomputing and redrafting the figure. Slight backwater effect existed in the cases: $d = 0.0313$, $S_f = 0.01$; and $d = 0.0625$, $S_f = 0.02$. The process of obtaining the average depths in Fig. 4 is described in a comprehensive manuscript entitled "Depth and Distribution Data for Flow in Model Street," by the writer. This material, with supporting experimental data, has been placed on file in the Engineering Societies Library. The latter manuscript also contains the derivation of the distribution of Q/Q_t (Fig. 6) and hydrodynamic quantities shown in Figs. 7, 8, 16, and 17.

Values of Q_s in Table 1 may be taken from Fig. 5(*a*), representing a constant value of S_f and three values of *d*, and from Fig. 5(*b*), representing a constant value of *d* and various values of S_f selected to vary the approach velocity. The slope, *S*, of the model itself was held constant for the present set of data. The small dispersion of data representing the several separate settings of the apparatus indicated by the different symbols along the curve for $d = 0.0313$ in Fig. 5(*a*) indicates the good consistency which was characteristic of such data. The apparatus was set at a large number of different slopes and adjustments in the period between the two extreme dates given in Fig. 5(*a*).

Values of *Q*, the inlet flow, were obtained by subtracting values of Q_s from those of Q_t. Values of $\frac{Q}{Q_t}$ were computed. The values of $\frac{Q}{Q_t}$ in Table 1 represent gravitational quantities as distinguished from distributional ones.

Fig. 6 shows distributional values of $\frac{Q}{Q_t}$ for $a_0 = 0.0460$. The graph has been made dimensionless by using values of the ratio $\frac{z_i}{z_t}$ for abscissas. In working up data for the figure it was found that the ratio $\frac{Q}{Q_t}$ for a given value of $\frac{z_i}{z_t}$ is constant for all values of Q_t to within a very small limit of error. $\left(\text{It is also true that } \frac{v}{Q_t} \text{ is constant for constant values of } a.\right)$ Hence, let

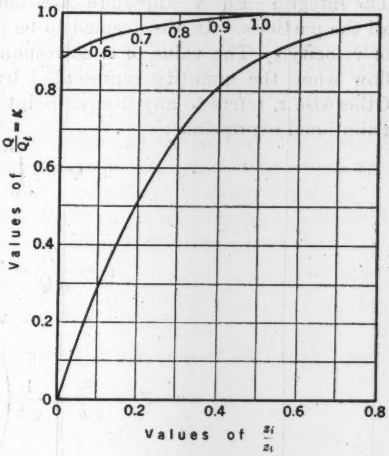

FIG. 6.—DISTRIBUTION VALUES OF Q/Q_t FOR $a_0 = 0.0460$

$$\frac{Q}{Q_t} = \kappa \qquad (7)$$

a constant for a given value of z_i.

The consistency found in the ratio $\frac{Q}{Q_t}$ for different values of Q_t and given values of a_0 confirms, to some extent, the accuracy of the depth-Q_t results obtained by the averaging process mentioned. The fact that the value of the ratio is known for all values of Q_t, and hence for $Q_t = 1.000$, makes it possible to use a single set of distributional curves in calculations.

Designating by the subscript 1 quantities corresponding to $Q_t = 1.000$, it will be shown that the required quantities G and U can be expressed in terms of G_1 and U_1, respectively, and Q^2_t. It is convenient to introduce at this point distributional expressions for the various quantities:

$$G = \rho \int_0^{z_i} v^2\, a\, dz \quad \text{(8)}$$

In Eq. 8, v represents the velocity at any value of z within the limits of the integral, a is the depth at that point, and z_i is the distance from the curb to the outer boundary of the filament of flow considered. (Actually v represents the apparent average velocity in a vertical line and not the velocity at a point. The integral—Eq. 8—therefore does not strictly represent the momentum of all the particles. It was deemed to be permissible to ignore vertical variation of velocity.) The value of z_i corresponds to the outer boundary of the inlet flow when the quantity represented by the integral is a gravitational one. Otherwise z_i refers to any desired point in the channel. Continuing with distributional expressions:

$$Q = \int_0^{z_i} v\, a\, dz \quad \text{(9a)}$$

$$\bar{v} = \frac{G}{\rho\, Q} = \frac{\int_0^{z_i} v^2\, a\, dz}{\int_0^{z_i} v\, a\, dz} \quad \text{(9b)}$$

$$\mathbf{F} = \frac{\bar{v}^2}{g\, h} = \frac{1}{g\, h}\left(\frac{\int_0^{z_i} v^2\, a\, dz}{\int_0^{z_i} v\, a\, dz}\right)^2 \quad \text{(9c)}$$

$$\mathbf{R} = \frac{\bar{v}\, h}{\nu} = \frac{h}{\nu}\,\frac{\int_0^{z_i} v^2\, a\, dz}{\int_0^{z_i} v\, a\, dz} \quad \text{(9d)}$$

$$U = \rho \int_0^{z_i} z\, v^2\, a\, dz \quad \text{(9e)}$$

$$\bar{z}\, P = \frac{\gamma}{2} \int_0^{z_i} z\, a^2\, dz \quad \text{(9f)}$$

By Eq. 7, $Q = \kappa Q_t$; so that

$$\frac{dQ}{dz} = Q_t \frac{d\kappa}{dz} \qquad (10)$$

A differential of discharge can be written

$$dQ = v\,a\,dz \qquad (11)$$

It follows, then, that

$$v = \frac{1}{a}\frac{dQ}{dz} \qquad (12a)$$

Hence, by Eq. 10,

$$v = \frac{1}{a} \times Q_t \frac{d\kappa}{dz} \qquad (12b)$$

in which the quantity

$$\frac{d\kappa}{dz} = \frac{d\left(\frac{Q}{Q_t}\right)}{dz} \qquad (13)$$

represents the slope of a graph like Fig. 6, but having z_i instead of $\frac{z_i}{z_t}$ for abscissas. The value of v in Eq. 12*b* can thus be determined by a process that is theoretically exact. The accuracy of the result depends only on the accuracy of the data and the accuracy with which the slopes of the graph can be scaled. Therefore, the method does not involve the systematic error which results when, for example, it is assumed that the velocity at the midpoint between a pair of the vanes used in the distribution experiments referred to equals the increment of discharge divided by the increment of area between the vanes.

Putting the value of v from Eq. 12*b* in Eq. 8, keeping Q_t outside the integral sign (since Q_t is not a function of z) and canceling a, the result is

$$G = \rho\, Q^2_t \int_0^{z_i} \frac{1}{a}\left(\frac{d\kappa}{dz}\right)^2 dz \qquad (14)$$

The quantity under the integral sign is purely a function of z so that, when $Q_t = 1.000$, Eq. 14 becomes

$$G_1 = \rho \int_0^{z_i} \frac{1}{a}\left(\frac{d\kappa}{dz}\right)^2 dz \qquad (15a)$$

Hence,

$$G = G_1\, Q^2_t \qquad (15b)$$

From Eqs. 12*b* and 9*e*,

$$U = \rho\, Q^2_t \int_0^{z_i} \frac{z}{a}\left(\frac{d\kappa}{dz}\right)^2 dz \qquad (16a)$$

so that

$$U = U_1\, Q^2_t \qquad (16b)$$

By Eq. 12*b*, when $Q_t = 1.000$,

$$v_1 = \frac{1}{a}\frac{d\kappa}{dz} \qquad (17)$$

Values of $\frac{d\kappa}{dz}$ were scaled from a curve similar to Fig. 6. A graph of v_1 is shown in Fig. 7. Values for the graphs of G_1 and U_1 in Fig. 7 were obtained by plotting values of

$$\frac{dG_1}{dz} = \frac{\rho}{a}\left(\frac{d\kappa}{dz}\right)^2 \dots\dots\dots\dots\dots\dots (18a)$$

and

$$\frac{dU_1}{dz} = z\,\frac{dG_1}{dz} \dots\dots\dots\dots\dots\dots (18b)$$

against values of z and measuring the areas under the curves by means of a planimeter. Values of Q_1 are represented by the ordinates in Fig. 6, and, using the values of G_1 from Fig. 7, values of $\bar{v}_1$ are obtainable by dividing G_1 by $\rho\,Q_1$, and are plotted in Fig. 7. Values of $\bar{z}\,P$ in Fig. 8 were likewise obtained by measuring the areas under the graph of $z\,\frac{dP}{dz}$ as a function of z.

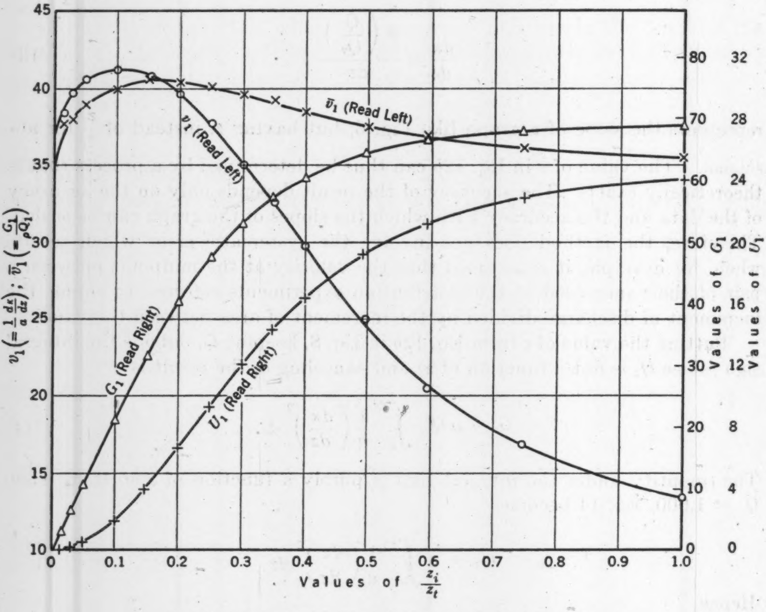

FIG. 7.—DISTRIBUTION DATA FOR a_0 = 0.0460, Q_t = 1.000

From the experimental values of $\frac{z_i}{z_t}$ in Table 1 and the graphs in Figs. 5 to 8, the other necessary gravitational data for beginning analysis can be obtained, and these are shown in Table 1.

V.—ANALYSIS

Form of the Function of **F**.—Since the phenomenon of flow into an inlet is principally gravitational in character, and since the flow is turbulent rather than laminar, K, in Eq. 6*b*, should vary principally with **F**, and to a minor extent with **R**. The dependent variable K is shown as a function of $\bar{v}$ and

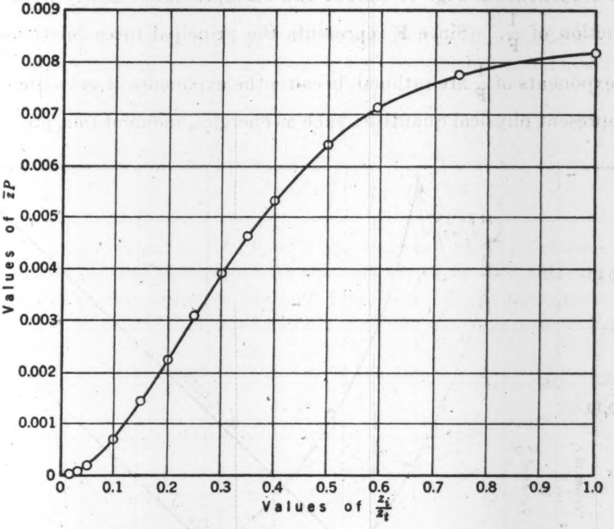

FIG. 8.—DISTRIBUTION OF MOMENT OF PRESSURE ($a_0 = 0.0460$)

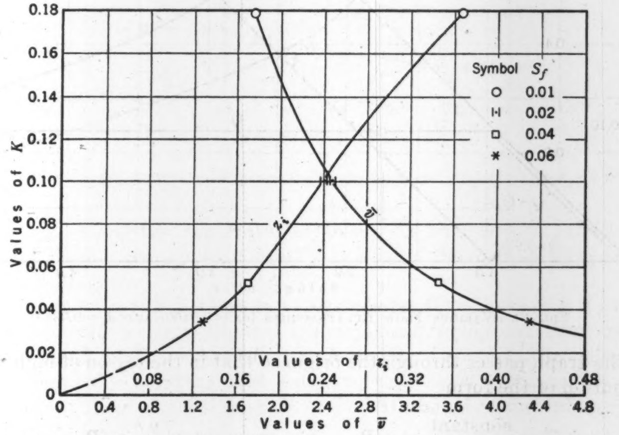

FIG. 9.—CORRESPONDING VALUES OF K, $\bar{v}$, AND z_i FOR $a_0 = 0.0460$ AND $d = 0.0313$

z_i in Fig. 9. Various flow relationships are shown in Fig. 10 and, in Fig. 11, K is shown as a function of **F**, and of $\left(\frac{1}{\mathbf{F}}\right)^{0.5} \frac{1}{\mathbf{F}}, \left(\frac{1}{\mathbf{F}}\right)^{1.5}$, and $\left(\frac{1}{\mathbf{F}}\right)^{2}$.

It is evident from Fig. 11 that K can be represented nearly by a straight-line function of $\frac{1}{\mathbf{F}}$. (Since **F** represents the principal force relationship only simple exponents of $\frac{1}{\mathbf{F}}$ are rational, because the exponents of velocities involved must represent physical quantities such as energies, momentums, etc.)[4] Moreover, the graph passes through the origin so that in the region of high velocities an equation of the form

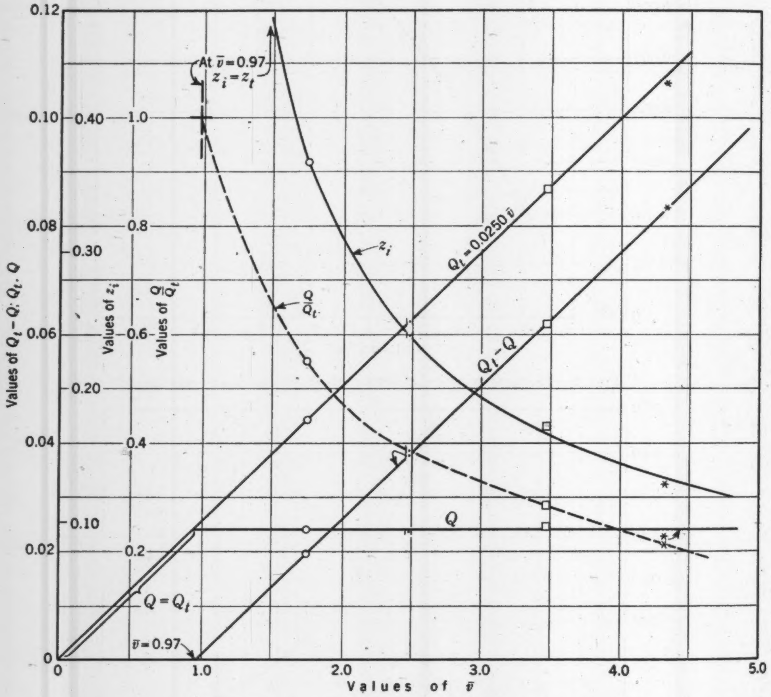

FIG. 10.—VARIOUS FLOW RELATIONSHIPS ($a_0 = 0.0460$; AND $d = 0.0313$)

$$K = \frac{\text{constant}}{\mathbf{F}} \times \phi(\mathbf{R} \ldots) = \text{constant} \times \frac{g\,h}{\bar{v}^2}\,\phi(\mathbf{R} \ldots) \ldots\ldots (19)$$

is correct. This form is also correct when g varies, because the left-hand member is

---

[4] "Engineering Mathematics," by Charles P. Steinmetz, McGraw-Hill Book Co., Inc., 1917, p. 213.

$$K = \frac{\bar{z}\,P}{U} = \frac{0.5\,\rho\,g \int z\,a^2\,dz}{U} \quad \dots\dots\dots\dots\dots\dots\dots (20)$$

In the region of low velocities, for an inviscid fluid, the right-hand member of Eq. 19 approaches infinity. By Eqs. 9*f* and 16*a*, the left-hand member is the distributional expression

$$K = \frac{\bar{z}\,P}{U} = \frac{\frac{\gamma}{2}\int_0^{z_i} z\,a^2\,dz}{\rho\,Q^2_t \int_0^{z_i} \frac{z}{a}\left(\frac{d\kappa}{dz}\right)^2 dz} \quad \dots\dots\dots\dots\dots\dots (21)$$

When $\bar{v}$ approaches zero, Q_t (the flow in the approach section between the curb and the crown) approaches zero. As the velocity, $\bar{v}$, of flow entering the inlet decreases, the corresponding value of z_i increases. If the maximum value of z_i is finite (as in actual fact it must be), then the denominator of Eq. 21 approaches zero while the numerator is finite. In this case, *K*, the left-hand member of Eq. 19, also approaches infinity so that the form of this equation is again satisfactory.

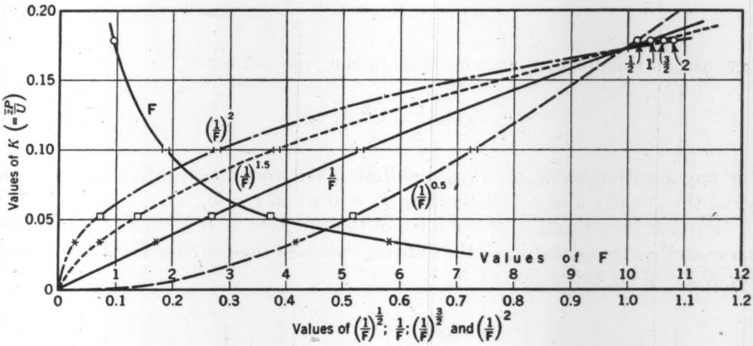

FIG. 11.—*K* AS A FUNCTION OF VARIOUS POWERS OF F (a_0 = 0.0460; AND d = 0.0313)

Theoretically, z_i can increase to values greater than those of z_t if the crown board is removed and the channel is extended laterally at crown elevation. Since the depth in the extended part is constant ($= a_c$), the velocity will become practically constant and equal to v_c a short distance beyond the crown. The values of the integrals in Eq. 21 then become infinite so that $K = \frac{\infty}{0 \times \infty}$. This indeterminate quantity can be evaluated by differentiating under the integral signs. (Each of the integrals is a function of z_i, its upper limit, considered as a variable. Moreover, z can be substituted for z_i so that, for example,[5] $\int_0^{z_i} z\, a^2\, dz = f(z)$, and $\frac{df(z)}{dz} = z\, a^2$.) Eq. 21 then becomes

$$K = \frac{\frac{\gamma}{2} z\, a^2}{\rho\, Q^2{}_t\, \frac{z}{a}\left(\frac{d\kappa}{dz}\right)^2} = \infty \quad\dots\dots\dots(22)$$

when $Q_t = 0$. In either case, therefore, K becomes infinite as $\bar{v}$ approaches zero $\left(\frac{1}{\mathbf{F}} \text{ approaches infinity}\right)$; for the time being it can be assumed that the form of function of **F** in Eq. 19 is correct.

Form of Function of **R**.—The form of function of **R** can now be studied by investigating the variation of $K\,\mathbf{F}$ with respect to **R**, since, by Eq. 19,

$$K\,\mathbf{F} = f(\mathbf{R}) \quad\dots\dots\dots(23)$$

It can be shown at once that the function of **R** is not of power form, such as

$$f(\mathbf{R}) = C\,\mathbf{R}^n = C\left(\frac{\bar{v}\,h}{\nu}\right)^n \quad\dots\dots\dots(24)$$

because, in this form, when $\nu = 0$, as in the "perfect fluid,"

$$K = \frac{C}{\mathbf{F}}\left(\frac{\bar{v}\,h}{\nu}\right)^n = \infty \quad\dots\dots\dots(25)$$

for any positive value of n—a manifest incongruity. Negative values of n yield the equally absurd relationship $K = 0$ when $\nu = 0$.

Further investigation of the form of the function of **R** will be facilitated by an analytical investigation of the limiting values of the distributional expression for $K\,\mathbf{F}$. This expression is

$$K\,\mathbf{F} = \frac{\frac{\gamma}{2}\int_0^{z_i} z\, a^2\, dz \left(\frac{\int_0^{z_i} v^2\, a\, dz}{\int_0^{z_i} v\, a\, dz}\right)^2}{\rho\, g\, h \int_0^{z_i} z\, v^2\, a\, dz} = \frac{1}{2}\, \frac{\int_0^{z_i} z\, a^2\, dz \left[\frac{\int_0^{z_i} \frac{1}{a}\left(\frac{d\kappa}{dz}\right)^2 dz}{\int_0^{z_i} \frac{d\kappa}{dz}\, dz}\right]^2}{h \int_0^{z_i} \frac{z}{a}\left(\frac{d\kappa}{dz}\right)^2 dz} \quad\dots(26)$$

canceling Q_t. Hence $K\,\mathbf{F}$ is independent of Q_t, a fact also confirmed by experimental data. In Eq. 26, if v is uniform,

$$K\,\mathbf{F} = \frac{\int_0^{z_i} z\, a^2\, dz}{2\,h \int_0^{z_i} z\, a\, dz} = \frac{\bar{a}}{2\,h} \quad\dots\dots\dots(27)$$

---

[5] "Advanced Calculus," by Edwin Bidwell Wilson, Ginn & Co. (Copyright 1911, 1912), p. 27.

in which $\bar{a}$ is a weighted or average value of a, and this value depends only upon the geometrical shape of the cross section and on the value of the limit z_i of the integrals. The locus of $K\,\mathbf{F}$ is thus, in this case, simply a geometrical curve. In Eq. 27, if the depth is constant $(= a)$, then $K\,\mathbf{F}$ has the constant value $\frac{a}{2\,h}$ for all values of z_i.

On the other hand, when v varies with z, $K\,\mathbf{F}$ is a function of v. Moreover, in Eq. 26, z_i decreases as the approach velocity increases, and when z_i approaches zero $K\,\mathbf{F}$ takes on the indeterminate form: $K\,\mathbf{F} = \frac{0}{0} \times \frac{0}{0}$. Resorting, as before, to differentiation, and substituting for a the quantity a_0, which it approaches in value,

$$K\,\mathbf{F} = \frac{\dfrac{z\,a^2}{2}\left[\dfrac{\dfrac{1}{a}\left(\dfrac{d\kappa}{dz}\right)^2}{\dfrac{d\kappa}{dz}}\right]^2}{h\,\dfrac{z}{a}\left(\dfrac{d\kappa}{dz}\right)^2} = \frac{a_0}{2\,h} = \frac{A_0}{2} \quad \ldots\ldots\ldots\ldots\ldots (28)$$

when $\mathbf{R}$ approaches infinity.

In like manner, when $\bar{v}$ approaches zero, or z_i approaches infinity, a approaches a_c, and $K\,\mathbf{F}$ takes on the indeterminate form: $K\,\mathbf{F} = \frac{\infty}{\infty} \times \frac{\infty}{\infty}$. Again, by differentiation and substitution, when $\mathbf{R} = 0$,

$$K\,\mathbf{F} = \frac{a_c}{2\,h} = \frac{A_c}{2} \quad \ldots\ldots\ldots\ldots\ldots (29)$$

Eqs. 28 and 29 furnish valuable additional data for supplementing the limited range of experimental values.

It is noteworthy that in the theoretical case of uniform velocity throughout the cross section and in the two cases representing limiting values of approach velocity K takes on the form of a Froude number: By Eq. 27, with v uniform—

$$K = \frac{\bar{a}}{2\,h} \times \frac{g\,h}{\bar{v}^2} = \frac{1}{2}\,\frac{\bar{a}\,g}{\bar{v}^2} \quad \ldots\ldots\ldots\ldots\ldots (30a)$$

by Eq. 28, with $z_i = 0$—

$$K = \frac{a_0}{2\,h} \times \frac{g\,h}{\bar{v}^2} = \frac{1}{2}\,\frac{a_0\,g}{\bar{v}^2} \quad \ldots\ldots\ldots\ldots\ldots (30b)$$

and, by Eq. 29, with $z_i = \infty$—

$$K = \frac{a_c}{2\,h} \times \frac{g\,h}{\bar{v}^2} = \frac{1}{2}\,\frac{a_c\,g}{\bar{v}^2} \quad \ldots\ldots\ldots\ldots\ldots (30c)$$

Derivation of the Equation.—For the experimental case being investigated $a_0 = 0.0460$, $a_c = 0.0035$, and $h = 0.1001$. Substituting these values in Eq. 28 and Eq. 29, there results: For $z_i = 0$,

$$K_0\,\mathbf{F}_0 = \frac{0.0460}{2 \times 0.1001} = 0.230 \quad \ldots\ldots\ldots\ldots\ldots (31a)$$

and, for $z_i = \infty$,

$$K_c\,\mathbf{F}_c = \frac{0.0035}{2 \times 0.1001} = 0.0175 \ldots\ldots\ldots\ldots\ldots (31b)$$

Moreover, it was observed in developing distribution curves that $K\,\mathbf{F}$ has the constant value $K_t\,\mathbf{F}_t = 0.133$ for all values of Q_t. These values are plotted, together with the four experimental ones, in Fig. 12. From the shape of the curve and the physical fact that $K\,\mathbf{F}$ must approach a constant value asymptotically when $\mathbf{R}$ approaches infinity, it is suggested that an hyperbola should fit the data. It may be a mere coincidence that the value of $K_t\,\mathbf{F}_t$ falls on the graph at a point on a line which bisects the angle between the asymptotes.

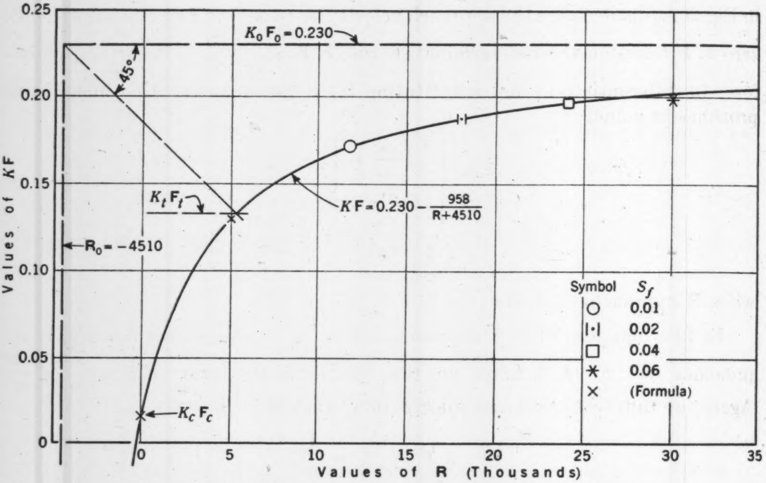

FIG. 12.—$K\,\mathbf{F}$ AS A FUNCTION OF $\mathbf{R}$ ($a_0 = 0.0460$; AND $d = 0.0313$)

The three-constant form of the equation for an hyperbola can be written

$$(\mathbf{R} - \mathbf{R}_0)\,(K\,\mathbf{F} - K_0\,\mathbf{F}_0) = -\,C_0 \ldots\ldots\ldots\ldots\ldots (32a)$$

in which $\mathbf{R}_0$ and $K_0\,\mathbf{F}_0$ are the asymptotes and C_0 is a constant of the hyperbola, or

$$K\,\mathbf{F} = 0.5\,A_0 - \frac{C_0}{\mathbf{R} - \mathbf{R}_0} \ldots\ldots\ldots\ldots\ldots (32b)$$

This is in the form of Eq. 23.

By Eqs. 29 and 32*b*, when $\mathbf{R} = 0$,

$$\frac{C_0}{\mathbf{R}_0} = -\,\frac{a_0 - a_c}{2\,h} = -\,\frac{y_c}{2\,h} = -\,0.5\,Y_c \ldots\ldots\ldots\ldots\ldots (33)$$

in which y_c is the crown height.

Only one constant, $\mathbf{R}_0$, remains to be determined; any one of the experimental sets of data is sufficient for its evaluation. Computation of a value corresponding to each set will provide comparative data by means of which the reliability of the method and the accuracy of the data can be judged. Solving for $\mathbf{R}_0$,

$$\mathbf{R}_0 = \frac{(K\,\mathbf{F} - 0.5\,A_0)\,\mathbf{R}}{K\,\mathbf{F} - 0.5\,A_c} \qquad (34)$$

Values of $\mathbf{R}_0$ for $d = 0.0313$ are computed in Table 2. The values in the last row in the table represent the arithmetical average values of $K\,\mathbf{F}$ and $\mathbf{R}$ for $S_f = 0.02$ and 0.04. These two sets are believed to be the most reliable. Hence, the value $\mathbf{R}_0 = -4{,}510$ will be considered satisfactory. By Eq. 33 $\left(\text{since } Y_c = \dfrac{0.0425}{0.1001} = 0.425\right)$, $C_0 = -0.5 \times 0.425\,(-4{,}510) = +958$. The equation representing $a_0 = 0.0460$, $d = 0.0313$ is then, by Eq. 32*b*:

$$K\,\mathbf{F} = 0.230 - \frac{958}{\mathbf{R} + 4{,}510} \qquad (35)$$

The check computations in Table 3 are obtained by inserting experimental values of $\mathbf{R}$ in Eq. 35. Thus, in all cases the values of $K\,\mathbf{F}$ computed from Eq. 35 are within 1.7% of the observed values of $K\,\mathbf{F}$. Comparison of the discrepancies on a basis of percentage of the small observed range (= 0.027)

of values of $K\,\mathbf{F}$ yields less than 6% for the first three slopes and less than 12% for $S_f = 0.06$. In the last case the value of z_i represents a distance less than that between the curb and the first vane by which the flow distribution was investigated, and a region, moreover, where the velocity profile curves rapidly. The data for $S_f = 0.06$, therefore, should be accredited less weight than the others. The results, in general, are considered satisfactory.

The equation for K is then

$$K = \frac{1}{\mathbf{F}}\left(0.230 - \frac{958}{\mathbf{R} + 4{,}510}\right) \quad \text{(36a)}$$

or, in general terms,

$$K = \frac{1}{\mathbf{F}}\left[\frac{a_0}{2\,h} + \frac{\dfrac{a_0 - a_c}{2\,h}\mathbf{R}_0}{\mathbf{R} - \mathbf{R}_0}\right] = \frac{0.5}{\mathbf{F}}\left(A_0 + \frac{Y_c\,\mathbf{R}_0}{\mathbf{R} - \mathbf{R}_0}\right) \quad \text{(36b)}$$

The Function When D Varies.—It can now finally be demonstrated that the form of function of $\mathbf{F}$ in Eq. 19 is consistent when D (and, therefore, h) varies, because, by Eq. 36*b*,

$$K = \frac{a_0\,g}{2\,\bar{v}^2}\left(1 + \frac{a_0 - a_c}{a_0}\,\frac{\mathbf{R}_0}{\mathbf{R} - \mathbf{R}_0}\right) \quad \text{(37)}$$

but,

$$\frac{\mathbf{R}_0}{\mathbf{R} - \mathbf{R}_0} = \frac{\mathbf{R}_0}{\mathbf{R}} + \left(\frac{\mathbf{R}_0}{\mathbf{R}}\right)^2 + \left(\frac{\mathbf{R}_0}{\mathbf{R}}\right)^3 + \cdots \quad \text{(38a)}$$

in which each term $\dfrac{\mathbf{R}_0}{\mathbf{R}}$ can be written

$$\frac{\mathbf{R}_0}{\mathbf{R}} = \frac{\dfrac{\bar{v}_0\,h}{\nu}}{\dfrac{\bar{v}\,h}{\nu}} = \frac{\bar{v}_0}{\bar{v}} \quad \text{(38b)}$$

Hence, when ν is the same for different values of h,

$$K = \frac{a_0\,g}{2\,\bar{v}^2}\left(1 + \frac{a_0 - a_c}{a_0}\,\frac{\bar{v}_0}{\bar{v} - \bar{v}_0}\right) \quad \text{(39)}$$

In Eq. 39, h does not appear in the right-hand member, and since, by Eq. 21, it is also absent from the left-hand member, it must be concluded that the form (Eq. 19) is correct. The small variation of K with h, which can be noted in Table 1, is in conformity with the small variation of $\bar{v}$ with z_i when Q_t is constant as shown in Fig. 7.

Shape Parameters.—In Eq. 36*b*, A_0, Y_c, and $\mathbf{R}_0$ are parameters whose values depend upon shape factors. The physical meaning of this equation is made more apparent when it is noted that, for high values of $\mathbf{R}$ (high velocities and small widths of inlet flow), K depends principally upon A_0; whereas, for lower values of $\mathbf{R}$ (lower velocities and wider filaments of inlet flow), K depends to an increased extent upon Y_c and $\mathbf{R}_0$.

The values of A_0 and Y_c depend upon the shape of the approach flow (if d is constant). When that shape is constant, other form factors such as length of inlet, width of depression, etc., govern the value of $\mathbf{R}_0$. Evidently K will be especially affected by variations of the latter form factors when approach velocities are low.

TABLE 4.—VALUES OF $\mathbf{R}_0$

d	h	D	$0.5\,A_0$	$0.5\,A_e$	KF	$\mathbf{R}$	$KF - 0.5\,A_0$	$(KF - 0.5\,A_0)\mathbf{R}$	$KF - 0.5\,A_e$	$\mathbf{R}_0$
0.0000	0.0688	0.000	0.334	0.0254	0.274	13,070	−0.060	− 783	0.249	−3,140

Values of $\mathbf{R}_0$ *for* $D = 0.000$ *and* $D = 0.476$.—The values of $\mathbf{R}_0$ in Table 4 were obtained by substituting experimental data in Eq. 34. Various relationships between $\mathbf{R}_0$, D, d, and $f(D)$ are shown in Appendix *A*.

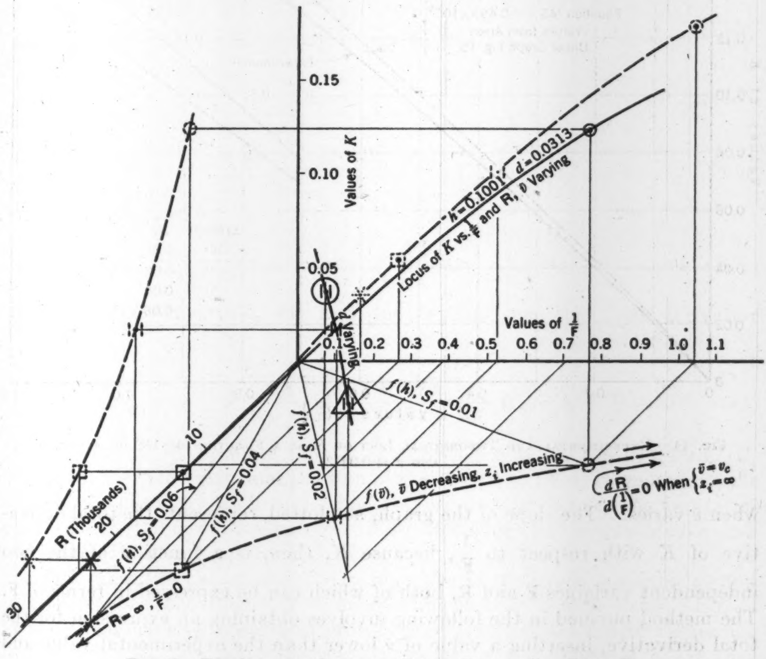

FIG. 13.—EXPERIMENTAL LOCUS OF K AS A FUNCTION OF F AND R

VI.—APPLICATION TO DESIGN

Eqs. 36 describe the experimental locus of K as a function of F and R. The locus is shown in three coordinates in Fig. 13. It is now desired to develop an expression by means of which the model results can be applied to a full-size prototype. This requires a separation of the effects of $\mathbf{F}$ and $\mathbf{R}$ so that a value of $\mathbf{R}$ can be used which will represent viscous conditions similar to those of a prototype. For model size and velocities this involves substituting a smaller value of ν.

Experimental values of K are plotted as a function of $\frac{1}{\mathbf{F}}$ (solid graph) in Fig. 14. It is evident that the values of K in this figure represent the combined effect of $\mathbf{F}$ and $\mathbf{R}$. This follows from the fact that $\mathbf{F}$ and $\mathbf{R}$ vary simultaneously when $\bar{v}$ varies. The slope of the graph, as plotted, represents the total derivative of K with respect to $\frac{1}{\mathbf{F}}$, because K, then, is a function of the two independent variables $\mathbf{F}$ and $\mathbf{R}$, both of which can be expressed in terms of $\mathbf{F}$. The method pursued in the following involves obtaining an expression for the total derivative, inserting a value of ν lower than the experimental value and then integrating. The result is shown as the broken graph in Fig. 14.

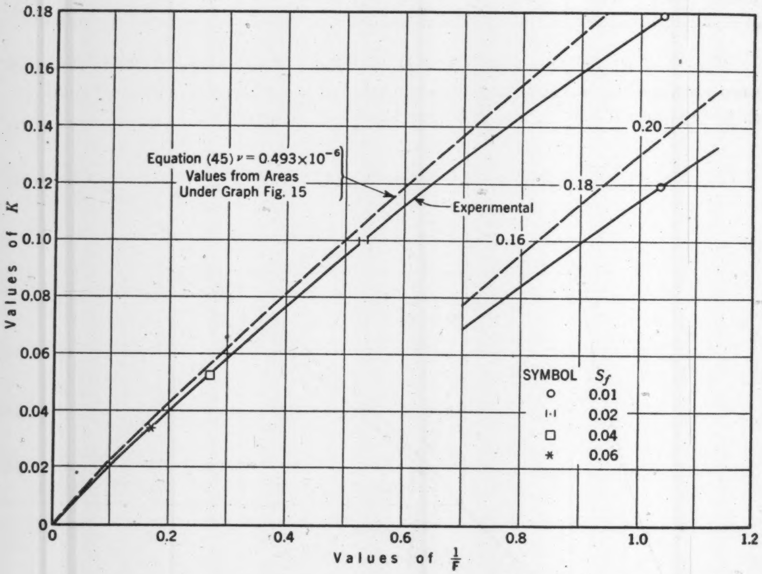

Fig. 14.—Experimental and Theoretical Loci of K as a Function of $1/\mathbf{F}$ (a_0 = 0.0460; and d = 0.0313)

An expression for the total derivative is:

$$\frac{dK}{d(1/\mathbf{F})} = \frac{\partial K}{\partial(1/\mathbf{F})} + \frac{\partial K}{\partial \mathbf{R}} \frac{d\mathbf{R}}{d(1/\mathbf{F})} \qquad \text{(40a)}$$

From Eq. 36*b*,

$$\frac{\partial K}{\partial(1/\mathbf{F})} = \frac{a_0}{2\,h} + \frac{\dfrac{a_0 - a_c}{2\,h}}{\mathbf{R}_M - \mathbf{R}_0}\mathbf{R}_0 \qquad (40b)$$

Note by comparison with Eq. 36*b* that this equals *K* **F**. The subscript *M* in Eq. 40*b* indicates the constancy of **R** ($\bar{v}$, *h*, and ν must have the model values—see Fig. 14—at the point concerned). Moreover,

$$\frac{\partial K}{\partial \mathbf{R}} = -\frac{1}{\mathbf{F}_M}\left[\frac{\dfrac{a_0 - a_c}{2\,h}\mathbf{R}_0}{(\mathbf{R}_\nu - \mathbf{R}_0)^2}\right] \qquad (41)$$

the subscript ν indicating that $\mathbf{R}_\nu$ is arbitrary with regard to ν, but in other respects it must be consistent with the constancy in **F**.

Reynolds' number may be expressed in terms of $\frac{1}{\mathbf{F}}$ in the following manner:

$$\bar{v}^2 = \frac{g\,h}{1/\mathbf{F}} \qquad (42a)$$

and

$$\mathbf{R} = \left(\frac{g\,h}{1/\mathbf{F}}\right)^{0.5}\frac{h}{\nu} \qquad (42b)$$

Thus

$$\frac{d\mathbf{R}}{d(1/\mathbf{F})} = \frac{g^{0.5}\,h^{1.5}}{\nu}\left[-\frac{1}{2}\left(\frac{1}{\mathbf{F}}\right)^{-1.5}\right] \qquad (43a)$$

Eq. 43*a* can be written

$$\frac{d\mathbf{R}}{d(1/\mathbf{F})} = -\frac{1}{2}\frac{\bar{v}\,h}{\nu} \times \frac{\bar{v}^2}{g\,h} = -\frac{1}{2}\mathbf{F}_M\,\mathbf{R}_\nu \qquad (43b)$$

Then inserting Eqs. 40*b*, 41, and 43*b* in Eq. 40*a*, the total derivative ($\bar{v}$ varying), is

$$\frac{dK}{d(1/\mathbf{F})} = \frac{a_0}{2\,h} + \frac{\dfrac{a_0 - a_c}{2\,h}\mathbf{R}_0}{\mathbf{R}_M - \mathbf{R}_0} + \frac{1}{2}\frac{\dfrac{a_0 - a_c}{2\,h}\mathbf{R}_0}{(\mathbf{R}_\nu - \mathbf{R}_0)^2}\mathbf{R}_\nu = \mathrm{A} + \mathrm{B} + \mathrm{C} \qquad (44)$$

If the value of $\mathbf{R}_\nu$ becomes infinite (ν approaches zero), the last term (C) approaches zero in value, and the sum of the other two (A + B) represents the slope of the graph for an inviscid fluid. Moreover, the sum of the two terms equals the partial derivative as given in Eq. 40*b*, which, as before stated, equals the value of *K* **F** as given by Eq. 36*b*.

With regard to the effects of viscosity, flow in the model is similar to flow in a prototype when Reynolds' number is the same in both systems. Eq. 44 thus may be made to represent a prototype by inserting the proper values of ν in the terms $\mathbf{R}_\nu$, but using experimental values of $\bar{v}$. Values of *K* are then given by

$$K = \int \frac{dK}{d(1/\mathbf{F})}\,d\!\left(\frac{1}{\mathbf{F}}\right) = \int\left[\frac{a_0}{2\,h} + \frac{\dfrac{a_0 - a_c}{2\,h}\mathbf{R}_0}{\mathbf{R}_M - \mathbf{R}_0} + \frac{1}{2}\frac{\dfrac{a_0 - a_c}{2\,h}\mathbf{R}_0\,\mathbf{R}_\nu}{(\mathbf{R}_\nu - \mathbf{R}_0)^2}\right]d\!\left(\frac{1}{\mathbf{F}}\right) \qquad (45)$$

The integral can be evaluated by measuring the area under the graph of the integrand, $\dfrac{dK}{d(1/\mathbf{F})}$, as a function of $\dfrac{1}{\mathbf{F}}$.

To obtain a value of ν, the case representing $S_f = 0.02$ is taken as an average one. For this case, $\mathbf{R} = 18{,}030$. Let it be assumed that the value of $\mathbf{R}$ for a prototype is about 500,000. (The exact value is not important, because the rate of variation of K with $\mathbf{R}$ in the region of $\mathbf{R} = 500{,}000$ is very small; $\mathbf{R}_\nu$ could be considered infinite without great error. The last term in Eq. 45 represents viscous effect.) The total flow, by Chézy's formula, in a prototype channel whose dimensions are $\dfrac{32}{3}$ times those of the model ($a_0 = 0.0460$), and for which Kutter's coefficient of roughness is $n = 0.013$, is $Q_{tP} =$ area $\times\, C_P\,(R_P\,S)^{0.5} = 3.40 \times 79\,(0.184 \times 0.02)^{0.5} = 16.3$.

Using subscripts M and ν to denote model and prototype (both to be simulated with model size, however), the relationship between Reynolds' numbers and values of ν (h and $\bar{v}$ being constant) is given by

$$\frac{\mathbf{R}_M}{\mathbf{R}_\nu} = \frac{\dfrac{\bar{v}\,h}{\nu_M}}{\dfrac{\bar{v}\,h}{\nu_\nu}} = \frac{\nu_\nu}{\nu_M} \qquad (46)$$

Since $\nu_\nu = \nu_M \dfrac{\mathbf{R}_M}{\mathbf{R}_\nu}$, $\nu_\nu = 13.7 \times 10^{-6} \times \dfrac{18{,}030}{500{,}000} = 0.493 \times 10^{-6}$.

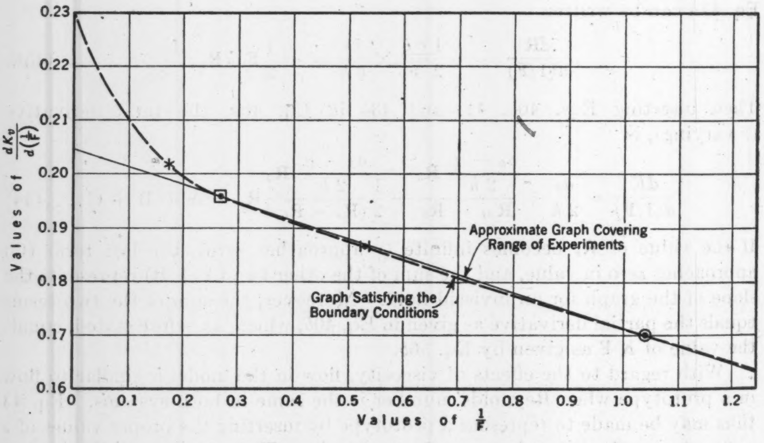

FIG. 15.—VALUES OF $\dfrac{dK_\nu}{d(1/\mathbf{F})}$ CORRESPONDING TO $\nu = 0.493 \times 10^{-6}$ ($a_0 = 0.0460$)

Values of $\dfrac{dK_\nu}{d(1/\mathbf{F})}$ corresponding to the value of $\nu = 0.493 \times 10^{-6}$ are calculated in Table 5 and have been plotted in Fig. 15 for the four experimental cases and the theoretical limiting case, $\frac{1}{\mathbf{F}} = 0$; that is, $\frac{dK}{d(1/\mathbf{F})} = \frac{a_0}{2\,h}$ (= 0.230). Fig. 15 also holds for $\nu = 0.322 \times 10^{-6}$ (see Table 5).

TABLE 5.—CALCULATION OF VALUES OF $\frac{dK_\nu}{d(1/\mathbf{F})}$

$$\left(\frac{a_0}{2\,h} = 0.230;\ \frac{a_0 - a_c}{2\,h}\mathbf{R}_0 = -\,958;\ \text{and}\ \mathbf{R}_0 = -\,4{,}510\right)$$

$\frac{dK_M}{d(1/\mathbf{F}_M)}$ (Eq. 44, $\nu_\nu = \nu_M$), of $\frac{a_i}{2\,h}$, and of $\frac{a_i}{2\,h} \times \frac{1}{\mathbf{F}}$. $\Big($Note that $\frac{a_i}{2\,h} \times \frac{1}{\mathbf{F}} = \frac{1}{2\,\bar{v}^2/(a_i\,g)}$, in which $\frac{\bar{v}^2}{a_i\,g}$ is a Froude number.$\Big)$ It may be noted that throughout the experimental range the corresponding values of $\frac{dK_\nu}{d(1/\mathbf{F})}$, $K\,\mathbf{F}$, and $\frac{\partial K}{\partial(1/\mathbf{F})}$ are substantially equal and that, for $S_f = 0.06$, values of the three quantities practically equal that of $\frac{a_i}{2\,h}$. Values of the total derivative, $\frac{dK_M}{d(1/\mathbf{F})}$, representing the actual experimental value of ν are approximately equal to values of $\frac{a_i}{2\,h}$, especially for the lower values of S_f (greater values of z_i).

In Fig. 15 a straight line represents, with sufficient accuracy, the three points representing $S_f = 0.01$, 0.02, and 0.04, but passes through neither the limiting point $\frac{dK}{d(1/\mathbf{F})} = 0.230$ at $\frac{1}{\mathbf{F}} = 0$, nor the other extreme, $\frac{dK}{d(1/\mathbf{F})} = \frac{a_e}{2\,h}$ ($= 0.0175$) at $\frac{1}{\mathbf{F}} = \infty$, obtainable from Eq. 44, when $\bar{v} = 0$—that is, when $\mathbf{R}_M$ and $\mathbf{R}_\nu$ equal zero.

Values of the integral Eq. 45 have been obtained from the areas under the dashed curve, Fig. 15. These are given in Table 7.

TABLE 7.—VALUES OF THE INTEGRAL, EQ. 45

$\frac{1}{\mathbf{F}}$	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.9	1.1
ΔK_ν	...	0.0219	0.0204	0.0197	0.0193	0.0189	0.0186	0.0182	0.0355	0.0342
K_ν	0	0.0219	0.0423	0.0620	0.0813	0.1002	0.1188	0.1370	0.1725	0.2067

Values of K_ν ($= \Sigma\Delta K_\nu$) from Table 7 are plotted in Fig. 14 and for the four experimental points their values are shown in Table 5, and in Table 6 together with the experimental and calculated values of K. Values of $K_\nu\,\mathbf{F}$ have also been calculated. Fig. 16 gives the corresponding values of $\frac{z_i}{z_t}$. It may be noted that except for the data representing $S_f = 0.01$, the values of $K_\nu\,\mathbf{F}$ are greater than the observed distributional values of $K\,\mathbf{F}$. The explanation of this is that the values of the equations derived herein depend upon conditions beyond the frictional effect of the curb. Such conditions have been represented in the region of the curb by the broken line in Fig. 16. The matter is not of practical importance since corresponding prototype values of z_i are smaller than are usually encountered.

Determination of the Model Case Corresponding to a Given Prototype.—In the approach channels of model and prototype, let the ratio of corresponding flows be the same. (This is in accordance with the usual assumption of model analysis technique.) Then

$$\frac{Q_P}{Q_{tP}} = \frac{Q_M}{Q_{tM}} \qquad \text{(47a)}$$

Assume, moreover, that for corresponding inlet flows the total flows follow Froude's law, or,

$$Q_{tP} = \left(\frac{32}{3}\right)^{2.5} \times Q_{tM} = 372\,Q_{tM} \qquad \text{(47b)}$$

Fig. 10 then yields the value of $\bar{v}$ $\left(\text{and, hence, of } \frac{1}{\mathbf{F}}\right)$ representing the inlet flow corresponding to the prototype total flow.

Design Example.—Let it be required to determine the quantity of flow that will enter an inlet 7 ft long, with a local depression 4 in. deep. The pavement is 36 ft wide, with a crown height of 0.45 ft and a longitudinal slope of 2%. The total flow between the curb and the crown is 16.3 cu ft per sec—the conditions corresponding to the model. (The flow in such a prototype, assuming Kutter's $n = 0.013$, is probably actually greater than 16.3, for the true mean depth is greater than an hydraulic radius determined by dividing the cross sectional area by the wetted perimeter.)

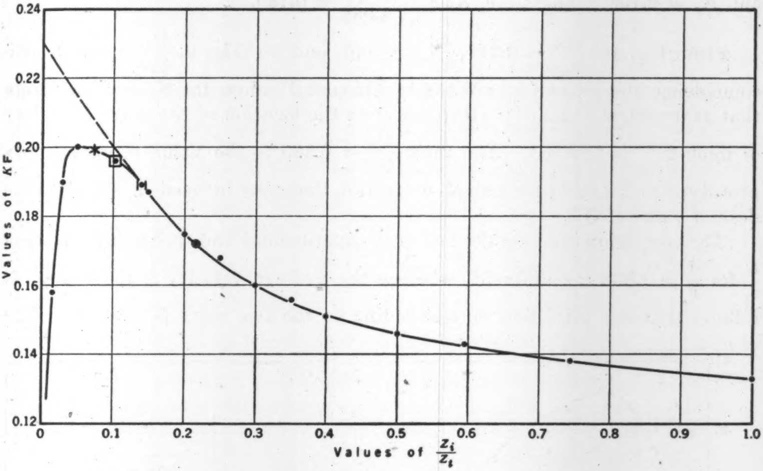

FIG. 16.—DISTRIBUTION OF KF FOR ALL VALUES OF Q_t ($h = 0.1001$)

The design process is as follows: By Eq. 47*b*, $Q_{tM} = \frac{16.3}{372} = 0.0438$. (Note that the experimental value representing $S_f = 0.01$ is $Q_{tM} = 0.0436$.) By Fig. 10, for this amount of total flow in the model, the average velocity of the part entering the inlet is $\bar{v}_M = 1.76$; so that: $\frac{1}{\mathbf{F}_M} = \frac{32.2 \times 0.1001}{(1.76)^2} = 1.038$. The value of ν representing the prototype value of $\mathbf{R}$ with model dimensions and velocity now can be computed. Since Froude's number is the same in model and prototype, and since $h_P = 1.07$, $\bar{v}_P = \left(\frac{32.2 \times 1.07}{1.038}\right)^{0.5} = 5.76$. Hence, for $\nu_P = 13.7 \times 10^{-6}$ (the experimental value for $S_f = 0.02$), $\mathbf{R}_P = \frac{5.76 \times 1.07}{13.7 \times 10^{-6}} = 450{,}000$. If Reynolds' number for model dimensions and velocities is to equal this, $\nu_\nu = \frac{1.76 \times 0.1001}{450{,}000} = 0.392 \times 10^{-6}$. Values of $\frac{dK_\nu}{d(1/\mathbf{F})}$ for this value of ν are shown in Table 5, and, since these agree with the values representing $\nu = 0.493 \times 10^{-6}$, the corresponding graph (Fig. 14) is satisfactory for design use in the present case.

For $\frac{1}{\mathbf{F}} = 1.038$, Fig. 14 yields $K_M = 0.179$; so that $K_M\,\mathbf{F} = \frac{0.179}{1.038} = 0.172$; and $K_\nu = 0.196$. Therefore, $K_\nu\,\mathbf{F} = \frac{0.196}{1.038} = 0.189$.

From Fig. 16: $\frac{z_{iM}}{z_{tM}} = 0.217$; $\frac{z_{i\nu}}{z_{t\nu}} = 0.140$; and, by Fig. 6, $\frac{Q_\nu}{Q_{t\nu}} = 0.385$. By coincidence the latter two are the experimental values for $S_f = 0.02$. Note that geometrical similarity with respect to the location of the outer boundary of inlet flow is ignored. The ratio $\frac{Q_\nu}{Q_{t\nu}} = 0.385$ is the value representing a prototype and, except for a small correction that may be needed, will yield the desired value of Q_P.

The correction involves the fact that experimental and theoretical values of $\frac{z_i}{z_t}$ for $\frac{1}{\mathbf{F}} = 1.038$ are different, whereas the average velocity is the same. It follows that the total flow corresponding to the two cases is different. The relationship between the two flows is found as follows: Two values, $\bar{v}_{\nu 1}$ and $\bar{v}_{M1}$, representing unit total flow, can be obtained for the two values of $\frac{z_i}{z_t}$ from Fig. 17. The ratio of these velocities equals the ratio of two other average velocities representing two different total flows, but a given value of $\frac{z_i}{z_t}$. This

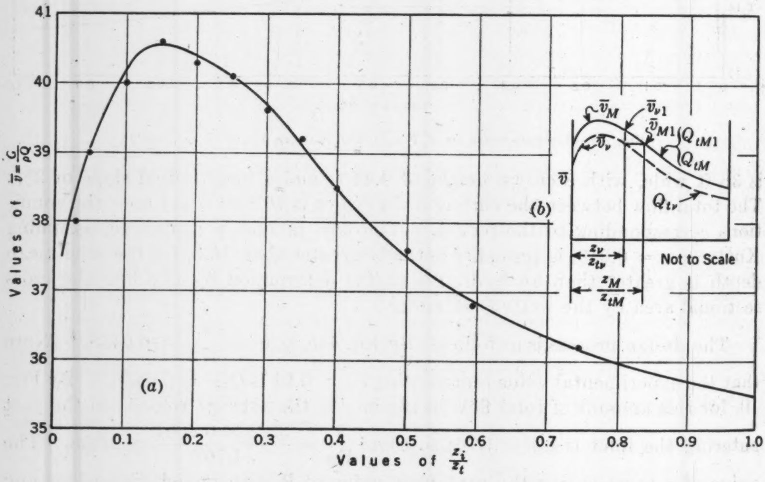

FIG. 17.—DISTRIBUTION OF $\bar{v}$ FOR UNIT TOTAL FLOW ($a_s = 0.0460$)

is shown schematically in Fig. 17(*b*). Hence

$$\frac{\bar{v}_{M1}}{\bar{v}_{\nu 1}} = \frac{\bar{v}_{\nu}}{\bar{v}_{M}} = \frac{Q_{t\nu}}{Q_{tM}} \quad \text{......................} \quad (48)$$

Fig. 17(*a*) yields, for $\frac{z_{iM}}{z_{tM}} = 0.217$ and $\frac{z_{i\nu}}{z_{t\nu}} = 0.140$, $\bar{v}_{M1} = 40.28$, and $\bar{v}_{\nu 1} = 40.55$; so that by Eq. 48 $\frac{Q_{t\nu}}{Q_{tM}} = \frac{40.28}{40.55} = 0.994$. Hence,

$$Q_{t\nu} = 0.994\, Q_{tM} \quad \text{......................} \quad (49)$$

Since $\frac{Q_{\nu}}{Q_{t\nu}} = 0.385$, $Q_{\nu} = 0.385 \times 0.994 \times 0.0438 = 0.0167$ (the correction is negligible in this case, and may be found to be so for all cases). The ratio $\frac{Q_{\nu}}{Q_{M}} = \frac{0.0167}{0.0239} = 0.699$ indicates that the flow that may be expected to enter a prototype inlet is about 70% of that which would be obtained by direct application of the model results.

Since, for equal values of **F**, $\frac{Q_P}{Q_{tP}} = \frac{Q_{\nu}}{Q_{t\nu}} = 0.385$, $Q_P = 16.3 \times 0.385 = 6.3$ cu ft per sec, the desired value of inlet flow in the prototype.

Where values of $\frac{Q}{Q_t}$ in the prototype are appreciably different from those in the model, it is necessary that the flow distribution be known. The variables K and $\bar{v}$ were selected with such a contingency in mind, but demonstration as to whether Froude's law applies in the case is not available at this time.

VII.—Conclusion

The result, $Q_P = 6.3$ cu ft per sec, obtained in the preceding example, is a reasonable quantity on a basis of experience, and in the absence of an error in the analytical method must be assumed to be correct. Nevertheless, confirmation of the result by means of an exactly similar larger, or full-scale, model is desirable.

The writer is aware that the method of solution used is not the only one, and, quite possibly, not the simplest, nor the best. Further investigation may disclose, for example, that the maximum velocity can be used as the characteristic velocity instead of $\bar{v}$. This would have the advantage of removing any doubt as to whether $\bar{v}$ is actually entirely independent of K. The maximum velocity can easily be obtained from Fig. 7, and it has the value

$$v_{\max} = 41.2\, Q_t \quad \text{......................} \quad (50)$$

The method of solution presented in this paper is intended to be used in future development of data for purposes of design. The necessary experimental data covering a fairly wide range of lengths of inlet, slopes of street, etc., have already been obtained.

Acknowledgments.—The experimental work upon which this paper is based was completed at the California Institute of Technology in 1937. The work was initiated and conducted mainly by the Bureau of Engineering, City of Los Angeles, through L. W. Armstrong, M. Am. Soc. C. E., the writer being in direct charge. The County of Los Angeles, through C. E. Arnold, Assoc. M.

Am. Soc. C. E., cooperated by furnishing an assistant. Valuable criticisms and suggestions have been contributed by R. T. Knapp, M. Am. Soc. C. E., V. A. Vanoni, Assoc. M. Am. Soc. C. E., and James Daily; and Hunter Rouse, Merit P. White, and W. J. Manetta, Assoc. Members, Am. Soc. C. E.

APPENDIX *A*

THE ASYMPTOTE, $\mathbf{R}_0$, AND THE FUNCTION OF *D*

The distributional expression for **R** given in Eq. 9*d* represents a range of values from $v = \infty$ and $z_i = 0$ to $v = 0$ and $z_i = \infty$. The value of **R** $(= \mathbf{R}_0)$ representing the asymptote, however, corresponds to a condition in which v has decreased to zero and beyond to minus infinity. Negative velocity represents a reversed direction of flow, that is, flow entering the street from the inlet. Although it may be possible by analytical means to derive the expression for $\mathbf{R}_0$ in a manner similar to that used in determining $K_0\,\mathbf{F}_0$, no such method has suggested itself.

The asymptote $\mathbf{R}_0$ does not occur at the value $\mathbf{R} = 0$, for at that point $K\,\mathbf{F} = \frac{a_c}{2\,h}$, a finite quantity, whereas at an asymptote the quantity must be infinite. This, moreover, is a reason that the three-constant form of hyperbolic equation is required rather than the two-constant form representing the "Second Hyperbolic Law":[6]

$$\frac{\mathbf{R}}{K\,\mathbf{F}} = c_1\,\mathbf{R} + c_2 \quad \text{.......................(51)}$$

THE FUNCTION OF *D*

In Eq. 36*b* the quantity within parentheses represents a product of functions of **R** and various dimensions. Dividing the coefficient of the term involving **R** by the constant term, $\frac{a_0}{2\,h}$, of the function, and rearranging, then yields (see Eq. 5)

$$\frac{K\,\mathbf{F}}{1 + \frac{a_0 - a_c}{a_0}\left(\frac{\mathbf{R}_0}{\mathbf{R} - \mathbf{R}_0}\right)} = \frac{a_0}{2\,h} = \tfrac{1}{2}\,\frac{h - d - c_s}{h} = \tfrac{1}{2}\,(1 - D - C_s) \quad \text{..(52)}$$

Hence,

$$\frac{2\,K\,\mathbf{F}}{1 + \frac{a_0 - a_c}{a_0}\left(\frac{\mathbf{R}_0}{\mathbf{R} - \mathbf{R}_0}\right)} + C_s = 1 - D \quad \text{............(53)}$$

The locus of values of the left-hand member plotted against values of *D* thus should yield a straight line. In Eq. 53 $\mathbf{R}_0$ is not constant. Values of the left-hand member for the three experimental cases are calculated in Table 8(*a*). When these values are plotted against values of *D*, the result is a straight line, confirming the arithmetic in calculations of the value of $\mathbf{R}_0$.

If, on the other hand, it is assumed that $\mathbf{R}_0$ is constant and has the values $-4{,}310$ ($d = 0.0313$, $S_f = 0.02$), and $-3{,}140$ ($d = 0.0000$, $S_f = 0.02$), then values of the left-hand member of Eq. 53, as calculated in Tables 8(*b*) and 8(*c*), produce slightly curved graphs when plotted against D. When plotted against D, R_0 is itself a function of D, and it is practically a straight-line function of D^4 and of d^2.

APPENDIX *B*

NOTATION

The following symbols are defined where they first appear and are assembled here for convenience of reference (see Fig. 1 for designation of dimensions):

$A_0 = \frac{a_0}{h}$, the approach-depth number;

a = depth at a distance, z, from the curb, in feet:

$\bar{a}$ = a weighted or average value of a;

a_0 = depth at curb at the approach section, in feet;

a_c = depth at the crown, or center line of street, in feet;

C = a coefficient:

C_0 = an hyperbolic constant;

$C_s = \frac{c_s}{h}$;

c = a coefficient; height of inlet opening, in feet: c_s = fall due to the normal slope of the model between the approach section and the center of the inlet, in feet;

$D = \frac{d}{h}$, the depth-of-depression number;

d = depth of depression, in feet;

e = subscript denoting excess flow, or overflow; height of overflow sill above normal gutter line produced, in feet;

$\mathbf{F}$ = Froude's number, $\frac{\bar{v}^2}{g\,h}$: $\mathbf{F}_M$ = Froude's number representing actual model flow;

h = head; the characteristic dimension; difference in elevation between the water surface at the approach section and the lip of the inlet at its midlength, in feet: h_P = head for prototype;

i = subscript indicating "inlet" or "integral";

K = the dependent variable, $\frac{\bar{z}\,P}{U}$:

$K_M = \frac{\bar{z}\,P}{U}$ for actual model flow;

$K_\nu = \frac{\bar{z}\,P}{U}$ for model dimensions and velocity, but a calculated value of ν;

l = length of upper end of depression (see Fig. 1);

n = width of overflow notch, in feet; an exponent;

R = hydraulic radius, in feet;

$\mathbf{R}$ = Reynolds' number, $\frac{\bar{v}\,h}{\nu}$:

$\mathbf{R}_M$ = Reynolds' number for actual model flow;

$\mathbf{R}_P$ = Reynolds' number for prototype flow;

$\mathbf{R}_\nu$ = Reynolds' number of prototype magnitude, but model dimension and velocity (ν calculated);

S = longitudinal slope of the model, in feet per foot: S_f = longitudinal slope of the approach flume, in feet per foot;

T = the roughness number, $\frac{t}{h}$;

t = height of roughness protuberances, in feet; subscript denoting "total";

$Y_c = \frac{y_c}{h}$, the crown height number;

y_c = the crown height;

z = distance from curb:

z_i = distance from curb to outer boundary of a filament of flow;

z_t = distance from curb to crown;

z_{iM} = distance, z_i, for model;

z_{tM} = distance, z_t, for model;

f, α, β, θ, etc. = function of;

$\kappa = \dfrac{Q}{Q_t}$.

DIMENSIONAL FORMULAS

G = momentum per second at the approach section of flow within the distance z_i from the curb; $M\,L\,T^{-2}$

g = acceleration of gravity, in feet per second per second $\left(= \dfrac{\gamma}{\rho}\right)$; $L\,T^{-2}$

P = hydrostatic pressure acting at the approach section on flow within a distance z_i from the curb, in pounds; $M\,L\,T^{-2}$

Q = rate of flow, in cubic feet per second at the approach section of flow within the distance z_i from the curb: $L^3\,T^{-1}$

Q_e = excess flow, or overflow;

Q_t = "total" flow or flow between the curb and the crown;

Q_P = flow, Q, in a prototype;

Q_M = flow, Q, in the model;

U = moment of momentum per second within a distance z_i from the curb at the approach section; $M\,L^2\,T^{-2}$

v = the apparent average velocity in a vertical line at a distance z from the curb, in feet per second: $L\,T^{-1}$

$\bar{v}$ = average velocity, or momentum per second per unit mass per second of flow within the distance z_i from the curb at the approach section $\left(= \dfrac{G}{\rho\,Q}\right)$; $L\,T^{-1}$

$\bar{v}_M$ = average velocity, $\bar{v}$, for the model;

$\bar{v}_P$ = average velocity, $\bar{v}$, for the prototype;

x = length of inlet;

$\bar{z}\,P$ = moment of hydrostatic pressure, P; $M\,L^2\,T^{-2}$

γ = specific weight, in pounds per cubic foot ($= \rho\,g = 62.4$ lb per cu ft); $M\,L^{-2}\,T^{-2}$

ν = kinematic coefficient of viscosity, in square feet per second $\left(= \dfrac{\mu}{\rho}\right)$: $L^2\,T^{-1}$

ν_P = actual kinematic viscosity for a prototype;

ν_r = kinematic viscosity representing a Reynolds number of prototype magnitude, but of model velocity and dimension;

μ = coefficient of viscosity; $M\,L^{-1}\,T^{-1}$

ρ = mass (slugs) per cubic foot $\left(= \dfrac{\gamma}{g} = 1.938\right)$. $M\,L^{-3}$

DISCUSSION

Ralph W. Powell,[7] **M. Am. Soc. C. E.**—A first reading of this paper gives one the impression that large caliber mathematical artillery has been brought to bear on a problem that should have succumbed to simpler methods. In default of a simpler method to suggest, perhaps such a criticism is ungracious; and this method of "distributional" analysis seems quite worth studying on its own account, entirely apart from the problem to which it is here applied. As the writer understands it, Mr. Tapley's method (omitting some of the details) is equivalent to the following. He has computed the kinematic viscosity of an imaginary, less viscous liquid (which would have produced Froudian similarity in his model) and the Reynolds number resulting from using the actual size and velocity of his model, but this imaginary viscosity instead of the actual viscosity. By running tests at several different slopes, he obtained enough variation in his mean velocities to give an appreciable variation in the Reynolds and Froude numbers and to derive a formula for the coefficient which he was studying in terms of **F** and **R**. His range of observed Reynolds numbers was only from 11,810 to 29,970, but by a very clever mathematical device (Eqs. 26 to 29), the validity of which the writer is not in a position to discuss at present, the range is extended to the entire field from zero to infinity. Therefore, the value of the coefficient for the aforementioned fictitious Reynolds number is obtained and the problem is solved. The writer wishes to make just a few observations.

It would seem that Eq. 6*b* is only one of the forms that Eq. 6*a* might take. For example, might not the equation be expressed as

$$K = C_{AD}\left[\alpha\,(\mathbf{F}) + \beta\,(\mathbf{R})\right] \ldots\ldots\ldots\ldots\ldots\ldots (54)$$

Of course, the experimental results seem to answer this particular question in the negative, but in general it must not be assumed that $\theta\ (\mathbf{F}, \mathbf{R})$ always can be put in the form $\alpha\ (\mathbf{F})\ \beta\ (\mathbf{R})$.

To the writer, the most interesting point of the paper is the use of a "momentum average" velocity instead of the usual "discharge average" in computing **F** and **R**—that is, instead of defining average velocity as discharge divided by area, the author has defined it as momentum divided by mass. This gives about 20% higher velocities in the examples of the paper. Since the ratio of $\bar{v}$ to v' for the different columns of Table 1 is quite constant, it would seem that this innovation would hardly affect the final result in this particular problem. However, it raises the very interesting question as to whether, in general, it would be an improvement over the ordinary usage. It would seem that it could hardly be expected ever to replace, entirely, the ordinary definitions of **F** and **R** because a knowledge of the velocity distribution would be required before either could be computed. It also raises the question as to whether one should ever use an "energy average"—the square root of twice the kinetic energy divided by the mass.

---

[7] Associate Prof. of Mechanics, Ohio State Univ., Columbus, Ohio.

The ratio $\frac{\bar{v}}{v'}$ has been variously denoted by β, α, and K_m by various authors. J. W. Johnson,[8] Assoc. M. Am. Soc. C. E., and M. P. O'Brien,[8,9] G. H. Hickox,[9] and R. W. Powell,[10] Members, Am. Soc. C. E., used β; S. M. Woodward, M. Am. Soc. C. E., and C. J. Posey,[11] Assoc. M. Am. Soc. C. E., used α; and Hunter Rouse[12] and Victor L. Streeter,[13] Assoc. Members, Am. Soc. C. E., used K_m. The value $\beta = 1.20$, which is indicated in Table 1, is quite high, but the true value is still higher because, as the author admits, he has neglected the variation of velocity in the vertical direction. Since this would be considerable, the true value of β was probably between 1.25 and 1.30—almost as much as for laminar flow. This must be due to the unsymmetrical cross section for, as the work of Professor Streeter,[13] shows, any reasonable assumption as to the frictional resistance would not account for such a high value if the section were symmetrical.

It should also be noted that in Eq. 8, and the other equations derived from it, special attention is required if any of the velocities are negative (that is, in the upstream direction). This has been pointed out by Professor Posey.[14]

A minor criticism of the paper is that the meaning of h in the definitions of **F** and **R** is not clear to the casual reader. Another is that, in a model this small, it would seem that, among the factors listed in Eq. 3*a*, surface tension would have to be included. In fact, it is the writer's opinion (without any rational reason to back it up) that the model should have been at least twice as large—that is, $\frac{3}{16}$ scale instead of $\frac{3}{32}$ scale.

G. S. TAPLEY,[15] ASSOC. M. AM. SOC. C. E.—The problem attacked in the paper is of a type upon which little has yet appeared in literature; features believed to be novel were included. It is regretted, therefore, that criticism, either for or against, was not more widespread.

Professor Powell's comments are very much to the point in several particulars. His statement that the method of distributional analysis seems worthy of study is believed to be particularly pertinent when, as in the case of storm-sewer inlets, the lateral distribution is so characteristically a feature of the phenomenon.

The study of distribution itself is also an active field at present. Attention is invited to the observed, practically perfect independence of the values of κ from the total flow Q_t in the model channel. Table 9 shows, for comparison, values of κ representing $S_f = 0.02$, or $Q_t = 0.0615$, and corresponding values of κ representing the average for $S_f = 0.01$, 0.02, 0.04, and 0.06, or

[15] Junior Civ. Engr., Bureau of Eng., City of Los Angeles, Los Angeles, Calif.

Q_t = 0.0434, 0.0615, 0.0870, and 0.1066. All data represent $a_0 = 0.0460$, an average obtained from a large number of observations.[16]

Inasmuch as Professor Powell calls attention to the writer's use of the momentum average, the following remarks upon average velocities may be in order: The so-called average velocity, "discharge divided by area," has been aptly called the "apparent average" velocity. It should be kept in mind that this velocity is an average one only in the uninteresting case where velocity does not vary throughout the cross section. The following mathematical expression shows this:

TABLE 9.—COMPARISON OF VALUES OF κ

Description	Values of z_i							
	0.168	0.339	0.508	0.674	0.841	1.003	1.257	1.700
κ (S_f=0.02)........................	0.278	0.517	0.690	0.805	0.882	0.928	0.969	1.001
κ (average)........................	0.280	0.518	0.693	0.810	0.886	0.932	0.970	1.000

$$v' = \frac{\int_0^A v\,dA}{\int_0^A dA} \qquad (55)$$

in which A represents area. Moreover, the physical conception is not clear; a particle of fluid cannot be described satisfactorily by its area of cross section, dA.

On the other hand, the expression for the momentum-average velocity, $\bar{v}$, is one for which the physical conception is grasped readily:

$$\bar{v} = \frac{\int v\,dM}{\int dM} = \frac{\int v\,\rho\,dQ}{M} = \frac{\rho \int_0^A v^2\,dA}{M} \qquad (56)$$

in which M represents mass per second, and Q represents volume per second. Each elementary mass of fluid is weighted by its particular velocity. The average, $\bar{v}$, is the velocity of all the particles moving as one mass when the corresponding momentum equals the aggregate of the momentums of all the individual masses moving at velocity v.

The expression for the energy-average velocity, $\bar{\bar{v}}$, may be obtained from

$$\bar{\bar{v}}^2 = \frac{\frac{1}{2}\int v^2\,dM}{\frac{1}{2}\int dM} = \frac{\int v^2\,\rho\,dQ}{\int \rho\,dQ} = \frac{\rho \int_0^A v^3\,dA}{\int_0^Q \rho\,dQ} \qquad (57)$$

---

[16] Values in Table 9 are from "Depth and Distribution Data for Flow in Model Street," by G. S. Tapley, Table 19. The original manuscript is on file at Engineering Societies Library, 29 West 39th Street, New York, N. Y.

Hence,

$$\bar{\bar{v}} = \frac{\left(\rho \int_0^A v^3\, dA\right)^{0.5}}{\left(\int_0^Q \rho\, dQ\right)^{0.5}} \qquad (58)$$

In Eq. 58 the physical conception is again not so clear as in the case of $\bar{v}$, because the denominator represents the square root of a mass per second. It is required, then, to state: $\bar{\bar{v}}$ is the velocity at which the square root of the mass per second moves when the energy of the total mass equals the sum of the energies of the individual particles.

Assuming that both energy-average and momentum-average velocities exist, the writer believes that the criterion for choice between them should be: Use the energy-average velocity when the phenomenon is properly and conveniently expressible in terms of work and energy; and use the momentum-average velocity when momentum and force are the proper mediums for expression.

Reference should be made to a bulletin of the National Bureau of Standards, dated July, 1942, regarding energy and momentum methods.[17] The bulletin calls attention to the long-standing nature of the controversy over the methods, and states that Boussinesq advocated the momentum method, whereas Coriolis advocated the energy method, Coriolis' view generally prevailing. The bulletin further gives the view of G. H. Keulegan that either method is correct, provided the proper interpretation is placed upon the operation, but that, practically, it is preferable to use the momentum method.

It should be emphasized that the ratio $\frac{\bar{v}}{v'}$, mentioned by Professor Powell, represents the ratio of the momentum-average velocity of the inlet flow to the discharge-over-area average velocity of the total flow. These quantities, therefore, are not comparable in the manner Professor Powell evidently believes they are, since they do not represent the same cross sections of flow.

In an investigation of backwater effect,[18] the writer found that the relationships in Table 10 hold for the total width of cross section, the area of cross section being 0.0298 sq ft. The ratio is thus constant, but less in magnitude than computed by Professor Powell. The writer did not feel warranted in ignoring a constant discrepancy even as small as 6%, because the quantity under investigation (Reynolds' number) was expected to make itself evident by only a feeble effect within the model range.

TABLE 10.—RELATIONSHIP BETWEEN $\bar{v}$ AND v'

Description	Values of S_f			
	0.01	0.02	0.04	0.06
$\bar{v}$	1.55	2.18	3.07	3.77
v'	1.46	2.06	2.90	3.57
$\bar{v}/v'$	1.06	1.06	1.06	1.05

Professor Powell inquires whether Eq. 54 could not have been used as well as Eq. 6*b*. The following arguments seem to prove that it could not, although some of the facts involved could not be anticipated without regard to the experimental data. All quantities of physics are products,[19] and any set of observations can be represented by a potential series.[20] Moreover, a product of a series is only another series. Eq. 54 evidently would apply to a series in which there were no terms such as **FR**; such terms are required in the experimental case because **F** and **R** vary simultaneously. In a similar case, Morrough P. O'Brien and George H. Hickox,[21] Members, Am. Soc. C. E., state that the unknown function should be considered as the product of two infinite series in the dimensionless groups.

---

[17] *Technical News Bulletin*, National Bureau of Standards, July, 1942, p. 50.

[18] "Inlet Flow with Backwater Effect," by G. S. Tapley, Table 9. The manuscript is filed with Engineering Societies Library, 29 West 39th Street, New York, N. Y.

Professor Powell is correct in stating that the meaning of *h* in connection with its use in **F** and **R** was not sufficiently emphasized. The dimension, of course, is the one selected as being descriptive of the characteristic phenomenon, gravitation, and it represents the fall of the water during its transit over the effective part of its course. Had viscosity been the principal consideration, another dimension would have been selected. When both gravity and viscosity are considered important, a single dimension is used in both the Froude and Reynolds numbers, but the dimension best representing the most important force is the one selected.

The writer agrees that it might have been preferable to use a larger model, but for the reason that difficulty was experienced in measuring depths accurately at the approach section, and not because of fear regarding the effect of surface tension. Considerable attention was given to the possible effect of surface tension because of the small size of the model, but it was concluded that the effect was inappreciable except in a few minor cases, such as when the overflow was approaching zero magnitude. However, in the case of submerged inlets (a subject not included in the paper), where the inlet operates as an orifice, surface tension was deemed to be an important consideration, and in an unpublished report entitled "Submerged Curb-Opening Storm Drain Inlets," the writer included it in the analysis by means of which the orifice coefficient was derived. The principal argument against a larger model, of course, is that time and expense items increase rapidly with increase in size. With a larger model it is possible, moreover, that it would have been difficult to have determined the form of the function of **R**, because the effect of viscosity becomes feebler with increase in size.

Backwater Effect.—Subsequent to completion of the analysis of free flow, an investigation of backwater effect[18] was undertaken. The following results of the latter investigation are submitted here as being substantiative, to some extent, of the correctness of the former analysis, and also for the value they may have in extending the range of conditions covered.

Following Eq. 36*a*, let

$$J = \frac{K\,\mathbf{F}}{0.230 - \dfrac{958}{\mathbf{R} + 4{,}510}} = \phi(\bar{v}, b, g, h) \ldots\ldots\ldots\ldots\ldots (59)$$

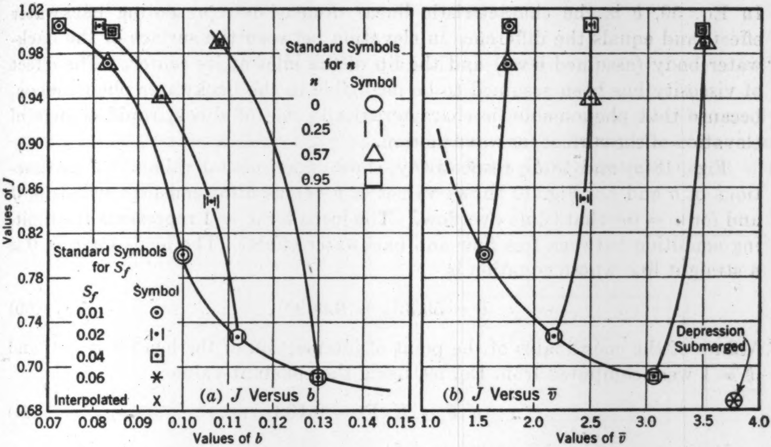

FIG. 18.—VALUES OF J AS FUNCTIONS OF b AND $\bar{v}$ ($a_s = 0.0460$)

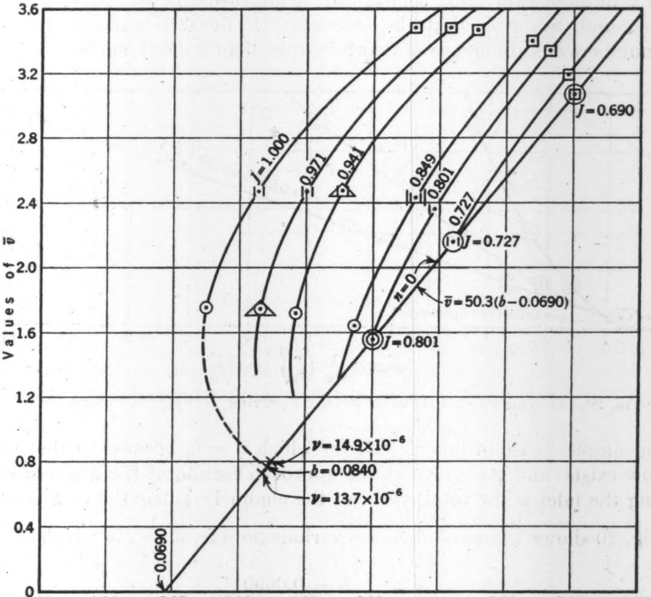

FIG. 19.—EXPERIMENTAL VALUES OF $\bar{v}$ AS A FUNCTION OF b, FOR CONSTANT VALUES OF J AND FOR $n = 0$

In Eq. 59, b is the characteristic linear dimension representing backwater effect, and equals the difference in elevation between the surface of the backwater body (assumed level) and the lip of the inlet at its center. The effect of viscosity has been assumed to be negligible in the backwater phenomenon, because that phenomenon is characteristically one of shock, rapid change of elevation of the surface, or wave motion.

Figs. 18(a) and 18(b), respectively, show experimental values of J as functions of b and $\bar{v}$. Fig. 19 shows values of $\bar{v}$ versus b for constant values of J and for $n = 0$—that is, no overflow. The locus for $J = 1$ represents the limiting condition between free flow and backwater effect. The locus for $n = 0$ is a straight line whose equation is

$$\bar{v} = 50.3\,(b - 0.0690) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (60)$$

Values of the coordinates of the point of intersection of the loci for $n = 0$ and $J = 1$ were computed from Eq. 59, using the constant value

$$K\,\mathbf{F} = K_t\,\mathbf{F}_t = 0.133 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (61)$$

and an average experimental value of ν.

It can be reasonably anticipated that the arguments in the function ϕ will combine in such a manner that J is expressed as a function of a Froude number and of a number expressing a geometrical dimension of the backwater body. It was found, however, that the characteristic linear dimension that enters these numbers is a difference of depths rather than a depth such as b.

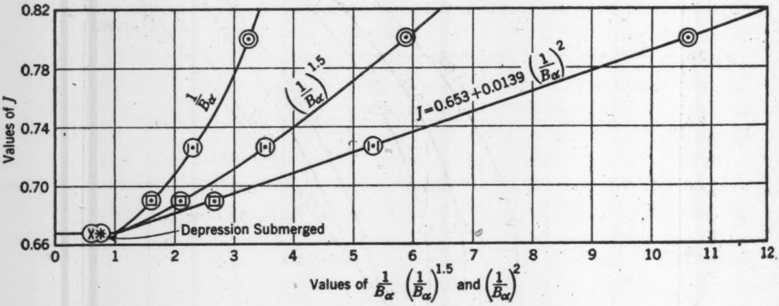

FIG. 20.—EXPERIMENTAL VALUES OF J AS A FUNCTION OF VARIOUS POWERS OF $\frac{1}{B_\alpha}$

The simplest case of flow is that for which $n = 0$, because in that case no overflow exists, and the width at the approach section of the filament of flow entering the inlet is the total width of the channel—z_i has the constant value z_t. Fig. 20 shows values of J versus various powers of $\frac{1}{B_\alpha}$, in which

$$B_\alpha = \frac{b - 0.0690}{h} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (62)$$

In Eq. 62, 0.0690 is the value of b when $\bar{v} = 0$ and $n = 0$, as shown in Fig. 19.

The equation for J in terms of B_α has the simple form

$$J = 0.653 + 0.0139\left(\frac{1}{B^2_\alpha}\right) \ldots\ldots\ldots\ldots\ldots\ldots (63)$$

Note that in Fig. 20 the data representing $S_f = 0.06$ correspond to the condition wherein the backwater wave has reached a point upstream far enough to submerge the depression completely, so that the velocity distribution at the approach section is no longer normal for the value of S_f.

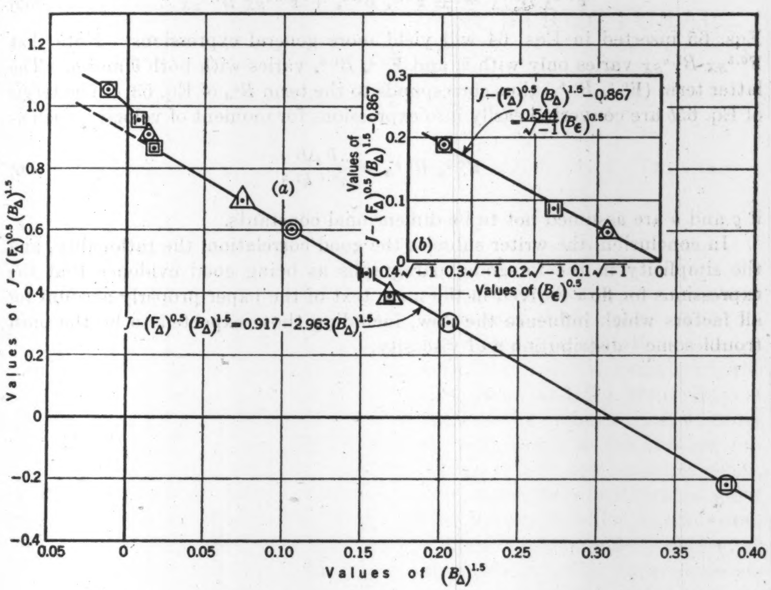

FIG. 21.—FLOW FACTORS FOR $b > 0.0840$ AND $b < 0.0840$ ($a_0 = 0.0460$)

It was found that, for conditions of flow other than those representing $n = 0$, other terms than B_α are necessary. The results are shown in Fig. 21 and are expressible by means of the linear relationships:

$$J - \mathbf{F}^{0.5}_\Delta\, B^{1.5}_\Delta = 0.867 - 2.963\,(B^{1.5}_\Delta - 0.0170) \ldots\ldots\ldots (64a)$$

for values of b greater than 0.0840, and

$$J - \mathbf{F}^{0.5}_\Delta\, B^{1.5}_\Delta = 0.867 + 0.544\,(-B_\epsilon)^{0.5} \ldots\ldots\ldots\ldots (64b)$$

for values of b less than 0.0840. In Eqs. 64: $\mathbf{F}_\Delta = \frac{\bar{v}^2}{g\,\Delta b}$; $\Delta b = b - 0.0774$; $B_\Delta = \frac{\Delta b}{h}$; $B_\epsilon = \frac{\epsilon\, b}{h}$; and $\epsilon\, b = b - 0.0840$. (Note that, by Eq. 61, the quantity $0.867 = 1 - K_t\, \mathbf{F}_t$.)

The difference in the parameters 0.0774 and 0.0840 is 0.0066, which is the fall in half the length of the inlet due to the normal slope of the model. This fact suggests the manner in which the length of inlet and slope of street enter the backwater function and should be useful when, later, these quantities are investigated as variables. It can be shown readily that

$$B_{\Delta} = B_{\epsilon} + B_{SX} = B_{\epsilon} + \frac{0.0066}{h} \qquad (65a)$$

and

$$\mathbf{F}^{0.5}_{\Delta}\, B^{1.5}_{\Delta} = \pm\, \mathbf{F}^{0.5}_{\epsilon}\, B^{1.5}_{\epsilon} + \mathbf{F}^{0.5}_{SX}\, B^{1.5}_{SX} \qquad (65b)$$

Eqs. 65 inserted in Eqs. 64 will yield more general expressions. Note that $\mathbf{F}^{0.5}_{SX}\, B^{1.5}_{SX}$ varies only with $\bar{v}$, and $\mathbf{F}^{0.5}_{\epsilon}\, B^{1.5}_{\epsilon}$ varies with both $\bar{v}$ and b. The latter term ($\mathbf{F}^{0.5}_{\epsilon}\, B^{1.5}_{\epsilon}$) thus corresponds to the term B^{2}_{α} of Eq. 63. The terms of Eq. 65*b* are converted easily into expressions for moment of velocity, such as

$$\mathbf{F}^{0.5}_{\Delta}\, B^{1.5}_{\Delta} = \frac{\bar{v}\, \Delta b}{g^{0.5}\, h^{1.5}} \qquad (66)$$

if g and h are assumed not to be dimensional constants.

In conclusion, the writer submits the good correlation, the rationality, and the simplicity in the foregoing paragraphs as being good evidence that the expressions for flow derived in the main text of the paper properly account for all factors which influence the flow, including those expected to be the most troublesome—distribution and viscosity.

MECHANICS OF CREEP FOR STRUCTURAL ANALYSIS

BY JOSEPH MARIN,[1] ASSOC. M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. A. HRENNIKOFF, C. A. P. TURNER, RALPH W. STEWART, AND JOSEPH MARIN.

SYNOPSIS

Under certain conditions in a stressed structural material, a continuous plastic deformation occurs with time for a constant stress value. This deformation is called "creep." The importance of creep in a particular design depends upon various factors as, for example, the material considered, the allowable stress used, the temperature of operation, and the desirability of maintaining a small deformation. For this reason the designer must consider the effect of creep in many applications, such as occurs in the turbine, oil-refining and automotive industries. In cases where high temperatures occur, changes in the stress distribution and deformations are sometimes so great that the need for considering effects of creep has been realized for several years. For normal temperatures, on the other hand, little has been done to determine the influence of creep as a factor in structural design. This paper is an attempt to analyze this problem. In developing methods of analysis for statically indeterminate structures it was necessary first to select a creep-stress law that could be used in place of Hooke's law. For this purpose a new creep-stress law is proposed in this paper. With a basic creep-stress relation for simple tension, theories for bending stresses and deflections in beams are developed. These theories form the basis for the slope-deflection and moment-distribution procedures developed for the analysis of statically indeterminate structures in the case of creep.

The importance of creep in structural analysis is twofold: First, there is the possibility that the creep deflection might be excessive; and second, there is, in the case of statically indeterminate structures, a change in the values of reactions and resisting moments when Hooke's law is replaced by a creep law. The significance of the creep deflection or the change in stress distribution in

---

NOTE.—Published in May, 1942, *Proceedings*.

[1] Prof., Eng. Mechanics, Pennsylvania State College, State College, Pa.

a particular design naturally will depend upon the material considered. Calculations indicate that in some cases a consideration of creep is important.

Some preliminary tests are reported in this paper in support of theories developed. It should be emphasized, however, that these theories will give only approximations, since the creep law is an approximate one. It must also be noted that there is great need for experimental work in this new field of study.

The importance of creep in structural analysis is particularly significant if stresses beyond the yield point are permitted or if such stresses are produced due to overloading. This is the case because there is evidence of creep for such stresses. A consideration of creep is necessary, therefore, for some structural materials and applications at both normal and elevated temperatures. Its importance is also magnified in view of the recent interest shown in designing structural parts stressed to the plastic range.

INTRODUCTION

When they are subjected to stress, engineering materials sometimes develop plastic deformations with time, called "creep deformations." At high temperatures these deformations are of such magnitude that they definitely influence design. Considerable test data have been obtained at high temperatures, particularly for materials used in the turbine and oil-refining industries. (See, for example, "Compilation of Available High Temperature Creep Characteristics of Metals and Alloys," A. S. M. E.—A. S. T. M., 1938.) Many attempts have been made to interpret these data for the purpose of selecting working stresses.[2] To the structural engineer, the behavior of materials at normal temperatures is of greater interest, but for such temperatures there is little information available. A brief review of the information on creep in simple tension and at normal temperatures will be made first. This study leads to the selection of a new creep-stress law in place of Hooke's law for the development of a mechanics of creep.

NOTATION

The letter symbols used in this paper are defined where they first appear and are assembled for reference in the Appendix.

SIMPLE TENSION; CREEP-STRESS LAW

Usually the simple creep-tension test is used for obtaining basic data on the creep behavior of engineering materials. In this test a specimen is subjected to a stress that remains constant, and the creep deformations are measured with time. With this information creep-time relations can be plotted for each stress value. Fig. 1 shows such plots for Aluminum Alloy 3S-3/4H tested at room temperature. These experiments in tension and others in pure bending have been reported in detail.[3] For many problems in design where creep is significant, it is necessary to select a working stress based on an allowable creep deformation in the estimated life of the machine or structural member. Industry cannot wait for lifetime test results, and it becomes necessary, therefore, to extrapolate test data that will apply for lengths of time not covered by the test results. This has led to a number of methods for interpreting the test data. For this purpose it is desirable to express a relationship for the creep deformation e_c in a time t for a unit stress s. When elevated temperatures must be considered, there is the additional variable of temperature.

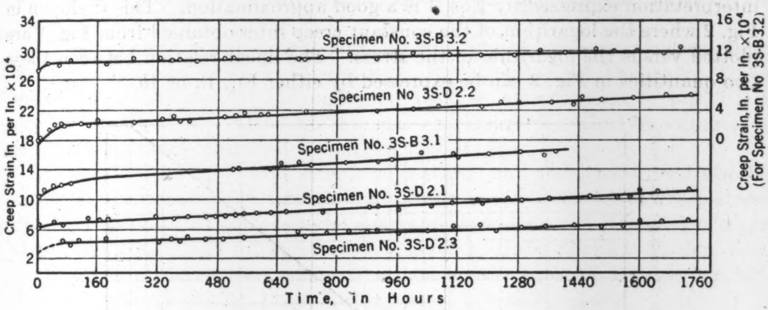

FIG. 1.—TENSION CREEP CURVES

Some of the methods for interpretation developed for elevated temperatures have been presented elsewhere.[2] More recently, procedures for interpretation of data have been proposed by S. H. Weaver,[4] C. R. Soderberg,[5] A. Nádai,[6] and others. A consideration of these methods shows that, although some of the methods fit a particular set of test data better than other methods, they do so by using a more complicated formula. If the creep-stress law is not a simple one, it leads to mathematical difficulties in developing a mechanics of creep, or the expressions deduced become too complicated for practical purposes. A creep law that satisfies the condition of simplicity and has considerable experimental support for many engineering materials at elevated temperatures is the one called the log-log creep-stress relationship. By this method, a constant creep rate is assumed. (See, for example, the many tests reported in "Compilation of Available High Temperature Creep Characteristics of Metals and Alloys," A. S. M. E.—A. S. T. M., 1938. These test results are plotted on a log-log basis and show an approximate linear plot.) In addition, a straight-line relationship is also assumed between the logarithm of the creep rate and the stress—that is,

$$C_n = a\,s^n \qquad (1a)$$

in which C_n = constant creep rate = $\frac{e_c}{t}$, and a and n are experimental constants. Eq. 1a also can be written:

$$e_c = a\, s^n\, t \qquad (1b)$$

Considering the behavior of engineering materials at normal temperatures, there are only a few experiments upon which to base a creep-stress law. It is desirable to review briefly some of these tests.

Experiments in tension[3] on Aluminum Alloy 3S-3/4H show that the log-log interpretation expressed by Eqs. 1 is a good approximation. This is shown in Fig. 2 where the logarithm of the constant creep rates obtained from Fig. 1 are plotted versus the logarithm of the stress. The linear relation between these two quantities in Fig. 2 can be expressed by either Eq. 1a or 1b.

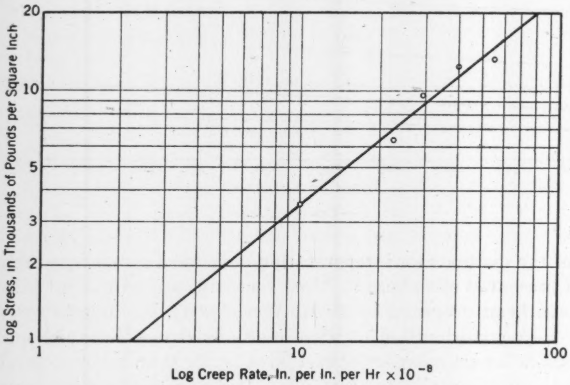

FIG. 2.—RELATION BETWEEN CREEP RATE AND STRESS

Creep tests on various engineering materials at normal temperatures were reported by R. G. Sturm, Assoc. M. Am. Soc. C. E., C. Dumont, and F. M. Howell.[7] These experiments were made on several aluminum alloys, soft and hard copper, and two steels. The material was in the form of sheets and wires. These tests show a log-log plot between the creep deformation and the time. Accordingly, the creep law proposed can be expressed essentially by the equation

$$e_c = F\, t^m \qquad (2)$$

in which F and m are experimental constants. By proposing Eq. 2, no attempt is made to give a general expression involving a variable stress.

Creep experiments on five steels were reported by H. J. French, H. C. Cross, and A. A. Peterson,[8] in which some of the tests were made at room temperature. These experiments were made on:

---

[7] "A Method of Analyzing Creep Data," by R. G. Sturm, C. Dumont, and F. M. Howell, *Transactions*, A. S. M. E., Vol. 58, 1936, p. A-63.

[8] "Creep in Five Steels at Different Temperatures," by H. J. French, H. C. Cross, and A. A. Peterson, *Paper No. 362*, Technical Papers of the Bureau of Standards, Vol. 22, 1927–1928.

One 0.24% carbon boiler-plate steel specimen;
One structural alloy steel specimen;
One tungsten-vanadium high-speed steel specimen;
One chromium "stain-resisting" steel specimen; and
One nickel chromium "austenitic" steel specimen.

Although sufficient experiments were not made for purposes of establishing a creep-stress law, these tests are significant in giving evidence of creep deformation in structural steel. They show that, for the structural steel tested, creep occurs when the stress is only slightly above the "proportional limit" of the material.

Creep of commercial leads at normal temperatures has been investigated by A. J. Phillips[9] and by H. F. Moore, B. B. Betty, and C. W. Dollins.[10] These experiments indicate that the log-log creep-stress law expressed by Eqs. 1 is a good approximation. Although this material is not of general importance, it is of interest in showing that the log-log plot applies.

Concrete is an important structural material and therefore should also be considered, if possible, in formulating a creep-stress law. Many creep-stress experiments on concrete in compression have been made. A summary of some of the test results and interpretations is given by J. R. Shank,[11] M. Am. Soc. C. E. The recommended creep-stress law on the basis of a study by Mr. Shank,[11] in terms of Eqs. 1 and 2, is

$$e_c = a\, s\, t^m \qquad (3)$$

An examination of the foregoing creep-stress equations shows that a general expression for these equations might be written

$$e_c = a\, s^n\, t^m \qquad (4)$$

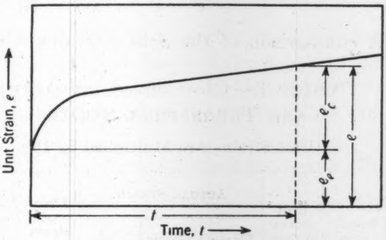

Fig. 3.—Creep-Time Curve

Eq. 4 seems to have considerable experimental support and has the advantage of simplicity when compared to some that have been proposed. One disadvantage of most creep-stress relationships, as in the case of Eq. 4, is that the elastic or initial deformation is not included. Referring to the deformation-time relation of Fig. 3, the total unit deformation e at a time t is made up of the elastic or initial deformation e_e plus the creep deformation e_c—that is,

$$e = e_e + e_c \qquad (5a)$$

---

[10] "The Creep and Fracture of Lead and Lead Alloys," by H. F. Moore, B. B. Betty, and C. W. Dollins, *Bulletin No. 272*, Univ. of Illinois Eng. Experiment Station, Urbana, Ill., 1935; see also "The Investigation of Creep and Fracture of Lead and Lead Alloys for Cable Sheathing," by the same authors, *Bulletin No. 306, ibid.*, 1938.

[11] "The Mechanics of Plastic Flow of Concrete," by J. R. Shank, *Proceedings*, A. C. I., 1936, pp. 149–180.

The value of the elastic or initial deformation will be assumed equal to

$$e_c = B\,s^p \qquad (5b)$$

For a material in which Hooke's law applies, $B = 1/E$ and $p = 1$, in which E = the modulus of elasticity of the material. Substituting the values of the deformations from Eqs. 4 and 5*b* in Eq. 5*a*, the unit deformation is

$$e = B\,s^p + a\,s^n\,t^m \qquad (6a)$$

Or, for a material for which Hooke's law applies,

$$e = \frac{s}{E} + a\,s^n\,t^m \qquad (6b)$$

Eqs. 6 define the total deformation in terms of the unit stress and the time. In addition, there are five experimental constants. This creep-stress law is used in the next section to develop a theory for stresses and deflections in the case of bending. It is found, however, that this leads to cumbersome expressions, making the formulation of structural mechanics in the case of creep very difficult. For this reason an approximation to Eq. 6*a* is suggested. This involves assuming the elastic or initial deformation to be expressed by $B\,s^n$ and determining B for the maximum stress—that is, B is determined from the equation $B\,s^2_{\max} = s_{\max}/E$. The total strain then will be assumed as

$$e = s^n\,(B + a\,t^m) \qquad (7a)$$

An indication of the accuracy obtained in using Eq. 7*a* is given by an analysis of the test data shown in Fig. 1. Using the results for specimens B3.2 and B3.1, $n = 1.22$, $m = 0.20$, $a = 3.75 \times 10^{-9}$, and $B = 1.04 \times 10^{-8}$. The value of B was determined on the basis of Hooke's law, as explained. The expression for the total strain as given by Eq. 7*a* then becomes

$$e = s^{1.22}\,(1.04 \times 10^{-8} + 3.75 \times 10^{-9}\,t^{0.20}) \qquad (7b)$$

A comparison of the actual strains with the theoretical values given by Eq. 7*b* is shown in Table 1. In determining the actual strains, the elastic strains were added to the creep strains. These deformations are for a time $t = 1{,}760$ hr. The percentage error in the value of the strains as given by Eq. 7*b* indicates that for these test data it is a good approximation. The approximation made in obtaining Eq. 7*a* produces a smaller error than is indicated in the test data. This is because the time covered by the tests is only a small fraction of the estimated life of the structure—that is, the test data cover a period of approximately two months, whereas the limiting deflection would be based on a time on the order of ten or twenty years. The elastic deformation is a very

TABLE 1.—COMPARISON OF ACTUAL AND THEORETICAL STRAINS

(Unit Strains Are Multiplied by 10^5)

Specimen	Unit stress (lb per sq in.)	ACTUAL STRAIN			Theoretical strain (Eq. 7*b*)	% error
		Creep strain (e_c)	Elastic strain (e_e)	$e_c + e_e$		
B3.2	3,472	35	29	64	56	−12
D2.3	6,227	70	52	122	115	− 6
D2.1	9,655	90	81	171	163	− 5
D2.2	12,321	110	102	212	271	−28
B3.1	13,130	174	109	283	284	0

small fraction of the creep deformation, and the error produced in using $B\,s^n$ for the elastic strain is therefore very small.

MEMBERS SUBJECTED TO BENDING

For a straight beam subjected to a pure bending moment M, as shown in Fig. 4, a theory for the stress distribution can be developed as in the case of the elastic theory. To do this it is only necessary to replace Hooke's law in the development, using the elastic theory with the creep-stress law expressed by Eq. 6*a*—that is, the following assumptions will be made:

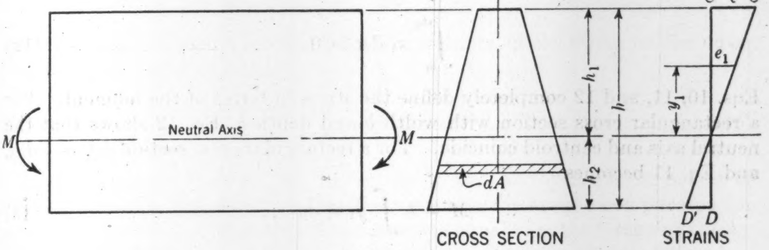

FIG. 4

(1) A transverse cross section of the beam originally plane and normal to the center line of the member remains plane after bending;

(2) For any fiber the strains are defined as in the case of tension by Eq. 6*a*;

(3) The creep-stress relations are identical for fibers in tension and compression at equal distances from the neutral axis; and

(4) The lateral compression between the fibers is negligible.

Assumption (1) has been verified by some experiments in bending.[12] By means of the foregoing assumptions and the conditions of equilibrium, a theory for the stresses and deflections in bending can be obtained. By the creep-stress law of Eq. 6*a*, the strains at distances y_1 and h_1 from the neutral axis are, respectively,

$$e_1 = B\,s^p{}_1 + a\,s^n{}_1\,t^m \qquad \text{(8a)}$$

and

$$e = B\,s^p + a\,s^n\,t^m \qquad \text{(8b)}$$

Assuming that plane sections remain plane, the strains are proportional to the distances from the neutral axis and

$$\frac{e_1}{e} = \frac{y_1}{h_1} \qquad \text{(9)}$$

Placing values of the strains from Eqs. 8 in Eq. 9,

$$y_1 = h_1\left(\frac{B\,s^p{}_1 + a\,s^n{}_1\,t^m}{B\,s^p + a\,s^n\,t^m}\right) \qquad \text{(10)}$$

---

[12] "Stresses and Deformations in Pipe Flanges Subjected to Creep at High Temperatures," by J. Marin, *Journal*, Franklin Inst., Vol. 226, November, 1938, p. 645.

For equilibrium the external and resisting moments are equal, or

$$M = \int y_1\, s_1\, dA \qquad (11)$$

In order to integrate Eq. 11, the position of the neutral axis must be defined. This is given by noting that the summation of stresses over the cross section of the beam must be zero, or

$$\int_{h_1}^{h_2} s_1\, dA = 0 \qquad (12)$$

Eqs. 10, 11, and 12 completely define the stress in terms of the moment. For a rectangular cross section with width *b* and depth *h*, Eq. 12 shows that the neutral axis and centroid coincide. For a rectangular cross section $dA = b\, dy_1$, and Eq. 11 becomes

$$M = b \int y_1\, s_1\, dy_1 \qquad (13)$$

To evaluate the integral in this equation it is necessary to determine dy_1 from Eq. 10. Placing the values of dy_1 and y_1 in Eq. 13 and integrating, the resulting equation is

$$M = \frac{b\, h^2}{2\,(B\, s^p + a\, s^n\, t^m)^2} \times \left(\frac{p\, B^2\, s^{2p+1}}{2\,p+1} + \frac{2\,p\,n\,a\,B\, s^{p+n+1}\, t^m}{p+n+1} + \frac{n\, a^2\, s^{2n+1}\, t^{2m}}{2\,n+1} \right) \qquad (14)$$

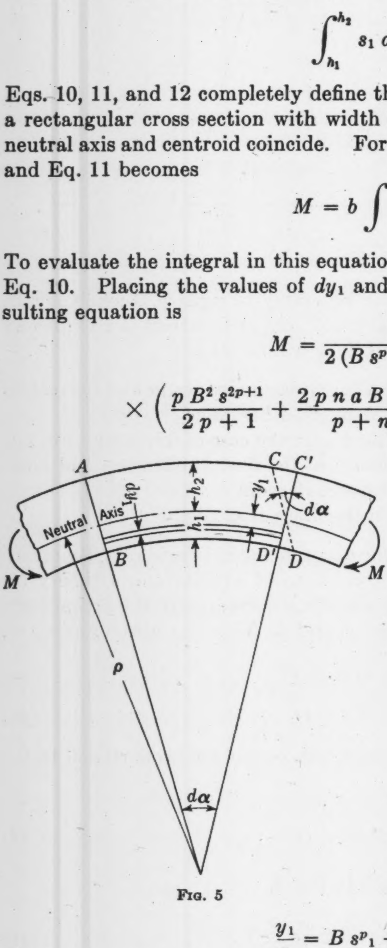

Fig. 5

The stress *s* on the outer fiber is defined by Eq. 14 in terms of the moment *M*, dimensions of the beam, and constants of the material.

In order to obtain an expression for the deflection in a beam subjected to pure bending, consider a section of a beam as shown in Fig. 5. The strains at distances y_1 and h_1 from the neutral axis in terms of the curvature are

$$e = \frac{h_1}{\rho} \text{ and } e_1 = \frac{y_1}{\rho} \qquad (15a)$$

in which ρ is the radius of curvature of a curved beam. Placing the values of e_1 from Eq. 8*a* in Eq. 15*a*, the curvature is defined by

$$\frac{y_1}{\rho} = B\, s^p{}_1 + a\, s^n{}_1\, t^m \qquad (15b)$$

Using the condition of equilibrium as given by Eq. 13, and placing the values of y_1 and dy_1 as obtained from Eq. 15b in this equation,

$$\frac{1}{\rho} = \frac{2}{h}(B\,s^p + a\,s^n\,t^m) \qquad (15c)$$

For small deflections the relation between the deflection y and the curvature is

$$\frac{1}{\rho} = \frac{d^2y}{dx^2} \qquad (15d)$$

The differential equation for the deflection in terms of the stress on the outer fiber is, by Eqs. 15c and 15d,

$$\frac{d^2y}{dx^2} = \frac{2}{h}(B\,s^p + a\,s^n\,t^m) \qquad (16)$$

A consideration of Eqs. 14 and 16 for the stress and deflection in beams of rectangular cross section shows that these expressions are too complicated for practical purposes. If the value of p is assumed equal to n, the foregoing theory is simplified. This is equivalent to assuming the approximate creep-stress law given by Eq. 7a. Placing $p = n$ in Eq. 14, the expression for the maximum stress is

$$s = \left(\frac{M\,h}{I}\right)\left(\frac{2\,n+1}{6\,n}\right) \qquad (17)$$

in which $I = b\,h^3/12$ = the moment of inertia of the cross section.

The differential equation for the deflection is given by substituting the value of $p = n$ in Eq. 16. Then

$$\left(\frac{D}{B + a\,t^m}\right)\frac{d^2y}{dx^2} = M^n \qquad (18)$$

in which

$$D = \frac{(2\,b)^n\left(\frac{h}{2}\right)^{2n+1}}{\left(2+\frac{1}{n}\right)^n} \qquad (19)$$

For the case where $t = 0$ and $n = 1$, Eq. 18 reduces to the equation given by the elastic theory. The value of D can be obtained in a manner similar to the foregoing for symmetrical sections other than rectangular. Eq. 18 can be used for determining deflections in beams in a manner similar to the usual double integration method. It is only necessary to integrate Eq. 18 twice and to obtain the constants of integration by using the boundary conditions of the particular problem. For example, in a simply supported beam of length l, subjected to a center concentrated load P, the deflection at a distance x from one end is

$$y = \frac{B + a\,t^m}{D}\left[\frac{x^{n+2}}{(n+1)(n+2)} - \frac{\left(\frac{l}{2}\right)^{n+1}}{(n+1)}x\right]\frac{P^n}{2^n} \qquad (20)$$

For a value of $x = l/2$, the maximum deflection is, by inspection or by Eq. 20,

$$y_{\max} = \frac{B + a\,t^m}{D} \times \frac{l^{n+2}}{2^{2(n+1)}} \times \frac{P^n}{n+2} \ldots\ldots\ldots\ldots\ldots (21)$$

The accuracy of the foregoing theory is indicated by a comparison between the measured and theoretical deflections in aluminum alloy beams subjected to pure bending.[3] These beams were subjected to pure bending moments of values shown in Table 2. They were of rectangular cross section of width $b = 0.50$ in. and depth $h = 1.00$ in., and the deflections were measured over a gage length $l = 8$ in. By Eq. 18 the expression for the deflection becomes

$$y = \frac{B + a\,t^m}{D} \times \frac{l^2}{8} \times M^n. \quad (22)$$

Using the values for the experimental constants obtained from the tension tests of Fig. 1, the theoretical values of the deflections, as given by Eq. 22, are shown in Table 2. The experimental values of these deflections are also listed. A comparison between the theoretical and experimental values shows that the theory gives a good approximation. In making this comparison the preliminary nature of these tests in this new field of study must be considered.

TABLE 2.—COMPARISON OF EXPERIMENTAL AND THEORETICAL DEFLECTIONS

Specimen No.	Moment (in-lb)	Theoretical deflection (in.)	Actual deflection (in.)	% error

A4	1,667	0.053	0.046	13

STATICALLY INDETERMINATE STRUCTURES

Knowing the relationship between the stresses and deformations in the case of simple tension and pure bending, theories for the analysis of statically indeterminate structures can be developed. It is convenient to discuss first statically indeterminate beams of one span.

(*1*) *Double Integration Method—Beams of One Span.*—For beams that are statically indeterminate, the values of the reactions and deflections can be found in a manner similar to the double integration method used for the elastic case—that is, essentially it is only necessary to integrate the differential Eq. 18 twice, first substituting the value of the moment M in terms of x for the particular problem. The constants of integration and the statically indeterminate reactions are then found by using the particular boundary conditions of the problem. The difficulties in this procedure are mathematical because in some cases the integration is not direct and in others considerable work is involved. These difficulties arise since the moment M in Eq. 18 is raised to a power n that is usually different from one, and the simplifications afforded in the elastic case by using the methods of superposition can no longer be used in this analysis. Some examples of statically indeterminate beams will now be discussed and the maximum moments compared with the "elastic" values.

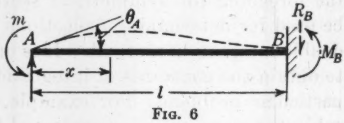

FIG. 6

Example 1.—A beam fixed at one end, simply supported at the other, and subjected to an end moment m is shown in Fig. 6. By Eq. 18 the deflection equation is

$$C_n \frac{d^2y}{dx^2} = M^n = (R_A\,x - m)^n \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

in which R_A = the reaction at point A, and

$$C_n = \left(\frac{D}{B + a\,t^m}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Integrating Eq. 23 twice,

$$C_n \frac{dy}{dx} = \frac{(R_A\,x - m)^{n+1}}{R_A\,(n+1)} + c_1 \ldots\ldots\ldots\ldots\ldots\ldots (25a)$$

and

$$C_n\,y = \frac{(R_A\,x - m)^{n+2}}{R^2_A\,(n+1)\,(n+2)} + c_1\,x + c_2 \ldots\ldots\ldots\ldots (25b)$$

in which c_1 and c_2 are constants of integration. Using the boundary conditions that the deflections are zero at both ends of the beam and the slope is zero at point B, the value of the reaction R_A is determined by the equation

$$R_A\,l\,(n+2)\,(R_A\,l - m)^{n+1} - (R_A\,l - m)^{n+2} + (-\,m)^{n+2} = 0 \,.\,. (26a)$$

Noting that $R_A\,l - m = M_B$, Eq. 26*a* can be written in terms of M_B—that is,

$$M^{n+2}{}_B + \left(\frac{n+2}{n+1}\right) m\,M^{n+1}{}_B + \left(\frac{1}{n+1}\right)(-\,m)^{n+2} = 0 \ldots (26b)$$

The value of the moment M_B as defined by Eq. 26*b* will depend upon the value of n. For different values of n the variation in M_B is represented in Table 3.[12a] The table also shows that there is a 44% increase in the moment at B for $n = 7$ over the value determined by the elastic theory. Values of n at elevated temperatures for steel have been reported as high as 9 so that it is possible to have an appreciable increase in the value of the moments over those values obtained by elasticity. The value of the bending stress, as determined by Eq. 17 for a rectangular section, is also modified, depending upon the value of n. In estimating the resultant effect it is necessary, therefore, to consider the influence of the change in moments as well as the change in stress distribution. Another important consideration is that of limiting the maximum deflection obtained from Eq. 25*b*.

TABLE 3.—VALUES OF M_B

Value of n	M_B	% increase
1 (elastic case)	0.5 m	0
3	0.65 m	30
5	0.67 m	34
7	0.72 m	44

Example 2.—A uniformly loaded beam, fixed at one end and simply supported at the other, is shown in Fig. 7. The differential equation for this problem, using Eq. 18, is

$$C_n \frac{d^2y}{dx^2} = \left(R_A\,x - \frac{w\,x^2}{2}\right)^n \ldots\ldots\ldots\ldots\ldots\ldots (27)$$

[12a] For discussion of errors, see closing comments on p. 479.

in which w is the load per unit of length. Proceeding in a manner similar to Example 1, an equation for the reaction R_A at point A can be determined. For a value of $n = 3$ the equation for R_A is

$$R^3_A - (1.25\,w\,l)\,R^2_A + (0.535\,w^2\,l^2)\,R_A - 0.078\,w^3\,l^3 = 0 \quad\ldots\ldots(28)$$

From Eq. 28 the value of R_A is $0.40\,w\,l$. For the elastic case, $R_A = 0.375\,w\,l$. The moment at the support for $n = 3$ is, by statics, $M_B = 0.10\,w\,l^2$ as compared to $0.125\,w\,l^2$ by the elastic case.

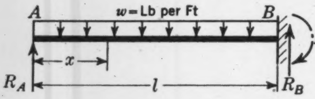

Fig. 7

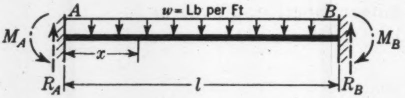

Fig. 8

Example 3.—For a beam fixed at both ends and subjected to a uniform load, as shown in Fig. 8, Eq. 18 becomes

$$C_n\,\frac{d^2y}{dx^2} = \left(\frac{w\,l\,x}{2} - M_A - \frac{w\,x^2}{2}\right)^n \quad\ldots\ldots\ldots\ldots\ldots\ldots(29)$$

Again following the procedure as explained for Example 1—namely, integrating Eq. 29 twice and applying the boundary conditions—an equation defining the value of M_A can be determined. For $n = 3$ this relation is

$$M^3_A - (0.25\,w\,l^2)\,M^2_A + (0.025\,w^2\,l^4)\,M_A - 0.00088\,w^3\,l^6 = 0 \quad\ldots(30)$$

Solving for this moment, its value is $M_A = 0.074\,w\,l^2$ as compared with $M_A = 0.0833\,w\,l^2$ for the elastic case.

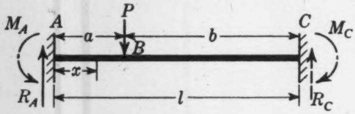

Fig. 9

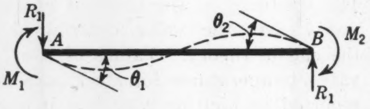

Fig. 10

Example 4.—For a beam fixed at both ends and subjected to a concentrated load (Fig. 9), it is necessary to write equations for both parts AB and BC of the beam. This leads to equations that are too complicated to present in this paper. If the load is considered at the center, $R_A = P/2$ and Eq. 18 need be written for only one half the beam. Thus, for AB,

$$C_n\,\frac{d^2y}{dx^2} = \left(\frac{P}{2}\,x - M_A\right)^n \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots(31)$$

Integrating this equation twice and applying the necessary boundary conditions, an equation for M_A can be found—namely,

$$\left(\frac{P\,l}{4} - M_A\right)^{n+1} - (-\,M_A)^{n+1} = 0 \quad\ldots\ldots\ldots\ldots\ldots(32)$$

Using this relation, $M_A = 0.13\,P\,l$ for $n = 3$, and $M_A = 0.14\,P\,l$ for $n = 5$. These values are higher than that of $0.125\,P\,l$ as found for the elastic case.

The foregoing examples show that the values of the statically indeterminate reactions and moments may be appreciably different from the magnitudes obtained for the elastic case. It may be necessary, therefore, to consider this difference in the design of statically indeterminate beams in which creep occurs.

(*2*) *Slope-Deflection Method.*—The slope-deflection method is one of the classical methods for structural analysis. For the condition of creep, equations similar to those for the elastic case can be derived. To obtain these equations, consider the beam AB in Fig. 10 simply supported at points A and B and subjected to moments M_1 and M_2 at the ends. By the slope-deflection method these moments are determined in terms of the slopes or rotations θ_1 and θ_2 at the ends of the beam. To do this, Eq. 18 can be used. Then

$$C_n \frac{d^2y}{dx^2} = M^n = (R_1\,x - M_1)^n \tag{33}$$

Integrating this equation twice,

$$C_n \frac{dy}{dx} = \frac{(R_1\,x - M_1)^{n+1}}{R_1\,(n+1)} + c_1 \tag{34a}$$

and

$$C_n\,y = \frac{(R_1\,x - M_1)^{n+2}}{R_1^2\,(n+1)\,(n+2)} + c_1\,x + c_2 \tag{34b}$$

Using the conditions that the deflections are zero at both $x = 0$ and $x = l$, the constants of integration c_1 and c_2 are determined. Then the slopes θ_1 and θ_2 are the values of dy/dx at $x = 0$ and $x = l$, respectively, as found by Eq. 34*a*. Noting also that $R_1 = (M_1 + M_2)/l$, the slope-deflection equations expressing the slopes in terms of the moments are:

$$\begin{aligned} C_n\,\theta_1\,(M_1 + M_2)^2\,(n+2)\,(n+1) &= (M_1 + M_2)\,(-\,M_1)^{n+1}\,l\,(n+2) \\ &\quad + l\,(-\,M_1)^{n+2} - (M_2)^{n+2}\,l \end{aligned} \tag{35a}$$

and

$$\begin{aligned} C_n\,\theta_2\,(M_1 + M_2)^2\,(n+2)\,(n+1) &= (M_1 + M_2)\,(M_2)^{n+1}\,l\,(n+2) \\ &\quad + l\,(-\,M_1)^{n+2} - (M_2)^{n+2}\,l \end{aligned} \tag{35b}$$

The solution of Eqs. 35 simultaneously for M_1 and M_2 offers difficulties not present in the elastic case. The conclusion must be, therefore, that the slope-deflection method is not suitable and that the modified moment-distribution method should be used.

(*3*) *Moment-Distribution Method.*—A study of the moment-distribution method of structural analysis as applied to members subjected to creep shows again the fundamental nature of the Hardy Cross method.[13] The basic character of this classic method remains unchanged for applications where creep must be considered, but it is necessary to determine the beam constants—namely, the fixed-end moments, the carry-over factors, and the distribution factors.

---

[13] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

The determination of the fixed-end moments has been explained herein in the section on the double integration method. To determine the carry-over and distribution factors it is necessary to determine the slope at the left end of the beam in Example 1, as shown in Fig. 6. This slope is the value of dy/dx in Eq. 23 for the value $x = 0$ or

$$C_n \theta_A = m^n \left\{ \frac{l\left[(-1)^{n+1} - (k)^{n+1}\right]}{(k+1)(n+1)} \right\} \qquad (36)$$

or

$$m^n = \frac{C_n (k+1)(n+1)}{l\left[(-1)^{n+1} - (k)^{n+1}\right]} \theta_A = J\, \theta_A \qquad (37)$$

in which

$$k = \frac{M_B}{m} \qquad (38a)$$

and

$$J = \frac{C_n (k+1)(n+1)}{l\left[(-1)^{n+1} - (k)^{n+1}\right]} \qquad (38b)$$

Eq. 37 expresses the moment m at A in terms of the slope θ_A at A. If the arrangement of members shown in Fig. 11 is considered, then, by Eq. 37,

$$M^n_{ab} = J_{ab}\theta_a; \quad M^n_{ac} = J_{ac}\theta_a; \quad M^n_{ad} = J_{ad}\theta_a; \quad \text{and} \quad M^n_{ae} = J_{ae}\theta_a \qquad (39)$$

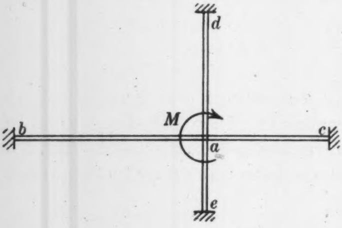

FIG. 11

For equilibrium,

$$M_{ab} + M_{ac} + M_{ad} + M_{ae} + M = 0 \qquad (40)$$

Substituting values from Eq. 39 in Eq. 40, and solving for θ_a,

$$\theta_a = -\frac{M^n}{(\Sigma J^{1/n})^n} \qquad (41)$$

Placing this value of the slope θ_a in Eq. 39, the ratios of the moments in the members to the applied moments—called the distribution factors—are:

$$\frac{M_{ab}}{M} = \frac{J^{1/n}{}_{ab}}{\Sigma J^{1/n}}; \quad \frac{M_{ac}}{M} = \frac{J^{1/n}{}_{ac}}{\Sigma J^{1/n}}; \quad \frac{M_{ad}}{M} = \frac{J^{1/n}{}_{ad}}{\Sigma J^{1/n}}; \quad \text{and} \quad \frac{M_{ae}}{M} = \frac{J^{1/n}{}_{ae}}{\Sigma J^{1/n}} \qquad (42)$$

or

$$D_f = \frac{J^{1/n}{}_p}{\Sigma J^{1/n}} \qquad (43)$$

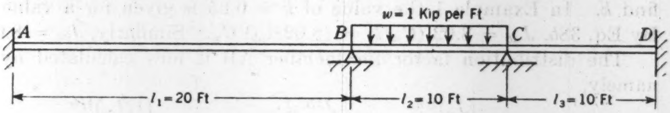
in which D_f is the distribution factor for any member.

The carry-over factor can be obtained by reference to Fig. 10 and Eq. 35b, which give the slope at point B in the beam AB. If this slope, $\theta_2 = \theta_B$, is placed equal to zero, the moment M_2 is then the moment at the fixed end of a beam AB, fixed at point B, simply supported at A, and subjected to a moment M_1 at A. The ratio M_2/M_1 is then the carry-over factor.

By Eqs. 35b, with $\theta_2 = 0$, the carry-over factor, $C_f = M_2/M_1$, is defined by the equation:

$$C^{n+2}{}_f + \left(\frac{n+2}{n+1}\right) C^{n+1}{}_f - \left(\frac{1}{n+1}\right) = 0 \qquad (44)$$

For values of n from 1 to 7 the carry-over factor varies from 0.5 to 0.72. With the fixed-end moments, distribution factors, and carry-over factors determined, the solution of some particular problem can be found, as illustrated by the following example.



(*a*) Computation for Moments at Supports

FIG. 12.—CONTINUOUS BEAM OF THREE SPANS

Example 5.[12a]—A continuous beam of three spans is shown in Fig. 12. The moments at the supports will be determined by the moment-distribution method for a value of $n = 3$, and these values will be compared with those for the elastic case.

In order to determine the moments at the supports, the beam constants must be obtained. The fixed-end moments for a uniform load and a value of

$n = 3$ are determined in Example 3. These moments are $M = 0.074\, w\, l^2 = 0.074 \times 1 \times 100 = 7.40$ kip-ft. The carry-over factor for a value of $n = 3$ is determined by Eq. 44. Its magnitude is $C_f = 0.61$. Finally, the distribution factors are found by Eq. 43, using Eq. 38*b* to determine J_p, and Eq. 38*a* to find k. In Example 1 the value of $k = 0.65$ is given for a value of $n = 3$. By Eq. 38*b*, $J_{ab} = 8.02\,(C_n/l) = (8.02/l_{ab})\,C_n$. Similarly, $J_{bc} = 8.02\,(C_n/l_{bc})$.

The distribution factor for member AB is now calculated by Eq. 43—namely,

$$D_{ab} = \frac{(J_p)^{1/n}}{\Sigma(J^{1/n})} = \frac{J^{1/n}{}_{ab}}{J^{1/n}{}_{ab} + J^{1/n}{}_{bc}} = \frac{(1/l_{ab})^{1/n}}{(1/l_{ab})^{1/n} + (1/l_{bc})^{1/n}} \quad \ldots\ldots (45)$$

or $D_{ab} = 0.44$; and similarly, $D_{bc} = 0.56$. Using the beam constants as given in Fig. 12(*a*), the moments at the supports are found. In Fig. 12(*b*) these moments are determined for the elastic case for the purpose of comparison. A comparison of these moments indicates that there is sufficient difference in the moments to warrant consideration in design. Other types of statically indeterminate structures can be analyzed in a similar manner.

A consideration of the energy methods of structural analysis shows that these methods cannot be applied in the case of creep because they require that the material be elastic. Other fundamental methods of structural analysis used in the elastic theory do not apply in the case of creep as, for example, the use of the law of superposition and the determination of influence lines by mechanical means. On the other hand, secondary stresses in the case of creep can be determined since the moment-distribution method can be applied.

Conclusion

In this paper a new creep-stress law is proposed for materials in which creep at both normal and elevated temperatures is important. Some experimental evidence is given and other data are cited that show the validity of the creep law assumed. A theory for stresses and deflections in members subjected to bending is developed and the values compared with creep test results. Theories are then derived for the analysis of statically indeterminate structures in cases where creep is present. Comparison of results with the elastic case shows that there may be an appreciable difference in the values of reactions and moments. It should be noted that there is considerable need for experimental work on this problem. In the meantime, however, this paper shows, in general, how structural analysis is modified when creep occurs in engineering materials.

APPENDIX

Notation

The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials, prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:[14]

---

[14] ASA—Z10a—1932.

A = area; dA = element of area;
a = experimental constant; also B, F, m, n, and p;
B = (see a)
b = breadth;
C_n = constant creep rate: C_f = carry-over factor;
c_1 and c_2 = constants of integration;
D = a dimension constant: D_f = distribution factor;
E = modulus of elasticity;
e = strain, unit deformation;
F = (see a);
h = height or depth of beam:
  h_1 = distance from neutral axis to top of beam;
  h_2 = distance from neutral axis to bottom of beam;
I = moment of inertia;
J = (see Eq. 38b): J_p, J_{ab}, etc., refer to given members of a structural arrangement;
k = a substitution constant (Eq. 38a);
l = span length: l_1, l_2, etc., denote lengths of adjacent spans 1, 2, etc.;
M = bending moment, subscripts denoting points about which moments are taken;
m = (see a);
n = (see a);
P = concentrated load;
p = (see a);
R = reaction at the point denoted by subscript;
s = unit stress;
t = time;
w = uniformly distributed load;
x = coordinate distance from the left support;
y = ordinate to an elastic curve; deflection of a beam;
α = angle of curvature between two points on a curved beam;
θ = slope of the elastic curve at points designated by subscripts; and
ρ = radius of curvature of beam.

DISCUSSION

A. Hrennikoff,[15] Assoc. M. Am. Soc. C. E.—The writer wishes to call attention to two mistakes made in the derivation of the theory of creep as presented in the paper of Professor Marin.

Creep Law.—For the basis of his theory the author (see Eq. 7*a*) selects the following relationship between the unit stress s and the unit strain e: $e = s^n (B + a\,t^m)$, in which the exponent n depends on the properties of the material and may assume any integral or fractional positive value above unity.

In order that a stress-strain relationship could be used to advantage in the derivation of a theory of flexure it should be valid both for the positive and the negative values of e and s—that is, both for the state of tension and the state of compression, a requirement which, of course, is satisfied by the familiar formula that expresses Hooke's. This condition, however, is true with regard to Eq. 7*a* only when the exponent n signifies an odd integer. On the other hand, when n assumes the value of an even integer or of a fraction, this equation under the conditions of negative stress becomes inconsistent, since the left-hand side of it is then negative, and the right-hand side positive when n is an even integer and imaginary when n is a fraction.

Eq. 7*a* would be correct, of course, from a mathematical point of view if e and s were used in the sense of the numerical values of stress and strain. This, however, was not the intention of the author, and with this interpretation Eq. 7*a* would scarcely be suitable for the purpose intended.

The error discussed herein leads to inconsistencies in further derivations. Thus, the basic differential equation (Eq. 18) relating the value of the bending moment in the beam with the value of the curvature of the elastic line $\frac{d^2y}{dx^2}$ is incorrect when n is an even integer or a fraction, since according to this equation a negative bending moment bends the beam in the same sense as a positive bending moment when $n = 2, 4$, etc., or produces an imaginary curvature when n is a fraction.

The same error is naturally carried into the solutions of the statically indeterminate structures, discussed later in the paper. Take, for instance, Example 1 depicted in Fig. 6. The symbols m and M_B in this figure denote the numerical values of the end moments, since the arrows representing these quantities are shown in their true directions. The relationship between these moments is expressed by Eq. 26*b*, an inspection of which shows that, should n be taken as a positive even integer, no positive values of m and M_B may be found to satisfy this equation—that is, to satisfy the conditions of the problem.

The author has been unlucky in selecting for the illustration of his theory in Table 3 the numerical values of $n = 1, 3, 5$, and 7—that is, those specific values for which his theory still holds. Had he used any other values of n the fallacy of his theory would have manifested itself in the absurdity of the numerical results.

Moment-Distribution Method.—The peculiarity of the stress-strain law used by the author makes superposition of deflections in beams caused by different loadings inadmissible. As an illustration of this principle, imagine a simply supported beam of a rectangular cross section loaded with a concentrated couple M_A on the end A and free from any other applied loads. The couple M_A causes rotation of the end A through an angle θ_A. Imagine now a new couple of the same magnitude M_A applied to the same end in the same direction. The second couple doubles the original moments caused by the first couple, as follows directly from statics, and doubles the original stresses anywhere in the beam, as may be concluded from inspection of Eq. 17. The strains, however, are more than doubled in view of the nature of the stress-strain law assumed, because the beam fibers are working now on the flatter parts of the stress-strain curve than they were before. Larger strains result in larger deformations, and the additional angle of rotation of the end A, produced by the second couple M_A alone, is larger, therefore, than the original angle θ_A; that is, the presence of the first state of stress in the beam has made the beam more flexible on the additional loading.

This behavior of the beam has an important bearing on the validity of the moment-distribution procedure, and it makes evident the fact that in the beam just considered the distribution factor on the second loading is smaller than on the first loading, provided that the other members attached to the same joint were still unstressed before the second loading. This dependence of the distribution factor (and of the carry-over factor as well) on the state of stress already existing in the beam may be demonstrated also for the fixed-ended beam by going through the necessary algebraic derivation. The author did not detect this dependence because his beam had been unstressed previous to the application of the end rotation. Dependence of the value of distribution factor on the state of stress in the beam makes the version of the distribution procedure presented by the author erroneous.

A modified moment-distribution procedure allowing for the state of stress existing in the beam is conceivable theoretically but scarcely possible in practice. It would be too laborious, since each step in the course of distribution would require a new set of values of the factors in each span of the structure.

The conclusion reached concerning the applicability of the method of moment distribution should not be surprising if one realizes that this method is based on the principle of superposition.

Summarizing the discussion it may be stated that the theory of creep as presented by Professor Marin is valid, from the mathematical point of view, only in the following two cases:

1. When the exponent n is an odd integer; and
2. When the signs of the bending moments are known beforehand in all parts of the structure. The value of n under these conditions may be arbitrary, but some modification in the author's formulas will be necessary if the sign of the moment is not the same everywhere in the structure.

The moment-distribution procedure is inadmissible even in cases when the theory holds.

It must also be kept in mind that the theory presupposes constant loads and seems to be inapplicable to simultaneous action of loads of different duration.

C. A. P. TURNER,[16] M. AM. SOC. C. E.—Professor Marin is to be congratulated for bringing into question the validity of treating Hooke's hypothesis as a law of nature. It may be doubted whether Hooke was first to present the suggestion that strain is approximately proportional to stress, since it appears in the Mariotte-Leibnitz theory of flexure following the publication of Galilei's problem.

At that early date, caloric or heat, light, electricity, and magnetism were regarded as imponderable chemical elements. This viewpoint (that of complete ignorance of intermolecular forces which oppose elastic change in form) warranted the adoption of the infinitesimal point hypothesis of Boscovich, which embodied a complete disregard of the temperature change incident to the application of the load.[17]

Now this temperature change which takes place upon the application of the load furnishes a measure of the magnitude of the load, as described by the writer in 1902.[18] The first practical recognition appears in the work of testing at the rolling mill where, by varying the speed of the machine in testing, the operator could satisfy engineers who wanted soft steel or others who wanted medium steel from the same metal with a different speed in testing. Thus, from the same bar, it was possible to develop, for soft steel, a 40,000-lb to 41,000-lb yield point with an ultimate strength of 58,500 to 60,000 lb per sq in., thus satisfying the college-trained engineer who wanted soft steel; and again, by increasing the speed in pulling the bar, a yield point of 44,000 to 45,000 lb per sq in., and an ultimate strength of 60,000 to 62,000 lb per sq in., could be developed, thus satisfying the engineer who wanted medium steel!

The energy of this temperature change upon application of the load depends on the final state and is independent of intermediate states as opposed to the external work, which is measured kinetically by the mean force times the deformation (by "kinetic," the initial equilibrium of the external and internal forces is meant).

The shift of internal energy resisting the external force is kinetically double the external work, and from this relation the physical properties of the metal may be coordinated.[19] As the elastic strain thus involves not only elongation but temperature change as well, it is apparent that the kinetic or instantaneous balance of equilibrium of external force and internal resistance will shift to the static balance as the thermo-elastic temperature change is dissipated by radiation. It further appears that to the extent the specimen is homogeneous the temperature change will be proportional to the applied force and, when this thermal limit of elasticity is exceeded, a range of imperfect elasticity is encountered before the development of the yield point of the metal. As this range of imperfect elasticity is developed, the cooling effect of tension is reduced until a radical heating effect is developed, with flow of the metal.

[19] "Elasticity, Structure, Strength and Chemical Action of Materials," by C. A. P. Turner, Pt. III.

The shift from kinetic to static equilibrium was discovered by Kelvin, who attributed the effect to viscosity instead of the radiation of temperature change incident to the application of the load. Kinetically, the internal energy shift is double the external work, but this kinetic external work is but five sixths of the static, as may be demonstrated in many ways by different formulas. Hooke's hypothesis is in no sense a law of nature; it is inexact unless the time element is taken into consideration.

In his work on the manufacture of steel, H. H. Campbell[20] found that by applying the load on the structural specimen at the rate of 0.1 in. per min, a yield point of 39,000 lb per sq in. was developed, whereas with the fast speed of the machine a yield point of 45,000 lb per sq in. was developed.

To cover the phenomena of viscosity within the thermal limit of elasticity, one may state that, if the load remains in place at a constant intensity until the temperature change on its application has been dissipated by radiation, the static elongation is proportional to the load applied and there is no creep or increased elongation. The situation is altered by residual strain from cold bending or other harsh treatment.

Residual strain presents a kind of elasticity of its own, best illustrated by cold bending some ⅜-in. square rods in a half circle with a 3-in. radius; then placing the horseshoe type specimen in a vise and sawing kerfs ⅛ in. deep and ½ in. apart, the distance between the ends of the bent piece will be decreased when taken from the vise. Reversing the process and sawing the kerfs on the outside of the bend, the ends will again spring in or will present a sharper curvature; then sawing the kerfs on both sides, the horseshoe will open out and decrease its curvature. This change in form is caused by upsetting the internal equilibrium between the internal residual and elastic areas of stress.[21]

When extensometer measurements of stresses in concrete floors were a fad with student investigators, it often happened that they measured, according to Hooke's law, residual changes in a form which they misinterpreted as elastic strains one and one-half to one and three-quarters times as great as the yield point of the metal they were investigating. (Measurements across cold bends or kinks in small rods give rise to erratic results.) This kind of residual creep has never received the attention it deserves.

Prior to Wohler's[22] experiments on repeated stress, the elastic limit of iron and steel was considered little less than the yield point of the metal. With range of stress from tension to compression exceeding ⅝ of the primitive yield point, failure occurred under a sufficiently large number of repetitions.

Instead of recognizing a range of imperfect elasticity beyond the natural elastic limit, the metaphysical range of stress formulas of Launhart and Weyrauch was developed based upon the assumption of fatigue within this natural limit where none was developed by experiment.

[21] "Elasticity, Structure, Strength and Chemical Action of Materials," by C. A. P. Turner, Pt. I, p. 55.

[22] *London Engineering*, Vol. XI, 1871.

With the passage of time these ranges of stress formulas have been discarded.

The writer's experiments on thermo-elastic measurement of stress place the thermal limit of elasticity as approximately five eighths of the yield point, in harmony with the work of Wohler. Creep or increased deformation will occur with time under stresses beyond the thermal limit of elasticity because, when this limit is exceeded, work has been done in displacing the molecular arrangement.

Recalescence points in melting or cooling of metals are recognized as points where the molecular formation undergoes modification. For example, soft ingot metal of the cubic system presents molecular kernels of eight atomic spheres. Upon rolling, this structure is broken down, and body-centered, nine-atom kernels appear. Again, drawing into fine wire, the body-centered formation changes to a face-centered formation, and the increase in strength under the law of attraction is as the square of the number of atoms in the kernel.

High-Temperature Creep.—At higher temperatures, a shift of molecular structure may take place in a manner similar to that occurring at the recalescent points of the metal, developing the so-called phenomena of creep at high temperature.

No natural phenomenon has been so much misrepresented by metaphysical hypotheses as that of elastic reaction. Volume, rather than elongation, is the correct measure of the effect of an axial force. Tension increases volume and compression reduces volume, and, although the same force causes equal volumetric changes whether from tension or compression, the temperature changes differ less in magnitude for tension and more for compression. In accordance with the law of volume, increase of volume is endothermic and decrease of volume is exothermic. This fundamental physical law destroys the basis of Lorentz and Einstein's calculation[23] of the interconvertibility of energy and mass and proves the irrationality of that characteristic energy of matter developed mathematically from a literal expression of Hooke's hypothesis. In a conservative system, the distribution of energy depends on the relation of masses and is irrespective of the individual unit, as demonstrated in the philosophical treatment of *The Encyclopædia Britannica.*[24]

The fantastic idea that one-quarter gram of matter has an intra-atomic energy equivalent to that developed by the engineer in burning 5,000 tons of coal is a metaphysical dream.[25] Not only has the elastic action of solids been confused in theory, but, in elastic resistance of gases to compression, physicists have invented a perfectly imaginary ideal gas in which the molecules have no volume and occupy no space. Because all gases have been liquefied and liquids are almost incompressible, one needs only to deduct the volume of the liquefied gas from the gross volume to find the net volume capable of compression in accordance with the laws of Charles, Boyle, and Gay-Lussac.

Professor Marin's creep theory for beams embodies the assumption that a plane section before bending remains plane after bending. Among the infinite number of sections in the length of the beam, one only in a simple beam remains plane after bending. That section divides the moment area in equal parts. As applied to the restrained and continuous beam, notwithstanding the creep correction of Professor Marin, the maximum tensile stresses at midspan and those over the support will be calculated anywhere from 15% to 30% greater than actual and the maximum compressive stresses will be approximately correct. The deflections will be much less than those computed in the restrained and continuous beams and greater than those computed by the ordinary formula for the simple beam.

The most curious inconsistency of the "Ut tensio sic vis" (extension proportional to force) lies in the fact that, under longitudinal compression, lateral extension occurs without any force or component of the applied force to account for it. Some have endeavored to explain this by a misconception of shearing stress; but the shears, as in beam action, can be developed only by principal stresses of opposite signs, and one of these principal stresses has no external force in its direction of action to account for its development.

The elastic temperature creep (that due to radiation of temperature change on application of the load) discloses the irrationality of the dynamic stress theory because the kinetic external work is but five sixths of the static; doubling it would be one and two thirds. Because the yield point before radiation is six fifths that after radiation is complete, the general effect of the suddenly applied load in developing the yield-point value is but one and one-third times the gradually applied static load, instead of twice the load, as taught in handbooks and textbooks of today.

Initial tests of newly cured reinforced-concrete beams disclose that steel stress times its lever under moderate loads is customarily 20% to 30% less than the applied moment. This inequality creeps out of existence under repeated loading. Textbook authors point to it as evidence of the operation of tensile resistance of concrete; but, by turning the concrete beam bottom side up, evidence of its insignificant value of concrete tension in flexure appears, requiring a more logical explanation.

As the concrete matrix crystallizes, it expands, inducing tensile stresses in the steel of a magnitude of 4,000 to 6,000 lb per sq in. The reaction to these steel stresses induces a state of residual compression in the concrete about the metal and, because the reaction to residual strain is antipodal to its elastic counterpart as shown by the cold-bent horseshoe bars, the resisting moment is that of steel stress times its lever plus residual compression in the concrete times the same arm, with the joint effect equilibrating the external moment.

Some deformed reinforcing bars indicate their top and bottom surface under their final pass through the rolls. If, on an 18-in. specimen, saw kerfs are made in the vise at ½-in. intervals, the bar will curve up slightly because the residual strain from rolling has been thrown out of balance by the reduction of sectional area. As in the example of the initially cured concrete beam, such residual strains are dissipated by repeated loading. After years of painstaking investigation, Bauschinger[26] concluded that sound metal, rather than being fatigued or brought nearer to rupture by alternating stresses from tension to compression within the natural elastic limits, was improved in elasticity, ductility, and tenacity.

An interesting example of apparent creep or downward motion of the neutral plane of reinforced-concrete beams was developed by the National Bureau of Standards[27] under the direction of the late Richard L. Humphrey, M. Am. Soc. C. E., in connection with the joint committee of the Society. In locating the position of the neutral plane, Mr. Humphrey and his committee assumed that this locus would be found where the longitudinal compression passed through zero, as in homogeneous beams, but that this locus crept downward as the load increased. In the reinforced-concrete beam, the shears between the tension of the steel and compression in the concrete are equilibrated at the steel instead of at the locus of the centers of rotation.

In the stress mechanism of a homogeneous beam, the lines of greatest compression above the neutral plane pair with the lines of greatest tension below it and intersect the neutral plane at 45°. In the concrete beam, because the shears are equilibrated at the bottom about the steel, the states of right shearing stress as centers of rotation are twisted 22.5° from their position in the homogeneous beams. This causes the lines of greatest compression to pair with the lines of greatest horizontal shear, intersecting the neutral plane at 22.5° instead of 45° so that the neutral plane is compressed longitudinally in proportion to the applied load, causing the locus of zero compression to creep downward as the load is increased. Elastic deflection of a concrete beam, therefore, increases more rapidly than the load because of this compression and shortening of the neutral plane.

Failure to grasp this relation has led to the unscientific conception of parabolic stress distribution in the compression zone and general confusion and mystery regarding the co-action of metal and concrete, limiting the conception of the field of investigation to that of concrete ribs functioning as steel beams would do.

No progressive achievement resulted from the deliberations of the Humphrey committee because they failed to grasp the idea of monolithic action in economic construction and the nature and distribution not only of shearing stresses in beams but of twisting stresses in plates. The stress mechanism of both homogeneous and reinforced-concrete beams and plates has been developed by the writer.[28]

The theory of elastic reaction as treated under Hooke's hypothesis is inconsistent with the statics of abstract forces because lateral extension occurs under longitudinal force with no component of that force to account for its development. In thermo-elastic theory this inconsistency disappears and

Young's modulus may be coordinated with specific heat; coefficient of expansion; unit weight; atomic weight and number; strength; and melting and boiling temperature through J (the mechanical equivalent), g (the gravitational constant), the gas-volume coefficient (constant temperature), or the gas-pressure coefficient (constant volume).

Thermo-elastic theory, treating actual rather than imaginary substances, embodies nothing more complicated than common school arithmetic, which should render it popular with the poor student who has labored with the tedious differential equations of mathematical theory, unrelated to the physical properties of actual substances.

The college textbook theory of the nature of tension and compression embodies the spheres of exclusion developed in 1650, and the foundation of mathematical elasticity is the infinitesimal point hypothesis of Boscovich of that same modernistic date and generation.

Ralph W. Stewart,[29] M. Am. Soc. C. E.—The gradual increase in permanent deformation of a highly stressed structure, which the author calls "creep," has been given little attention in civil engineering literature. In reading this paper the writer was impressed with the fact that it contained valuable information on the subject.

In the writer's early practice he noticed that the 20-yr-old wooden joists in certain heavily traveled bridges had acquired a pronounced sag due to creep. For long beams continuous over a number of supports, the effect of creep obviously would tend to equalize the positive and negative moments after the manner of the plastic flow in an overstressed structure. In fact, the distinction between creep and plastic flow is narrow and seems to depend on the time element.

FIG. 15.—COMPARATIVE ANALYSIS FOR THE ELASTIC CASE (F.E.M. = Fixed-End Moment)

In designing machinery there is evidently justification for including the effect of creep in the stress analysis, but in designing continuous bridges and building frames the neglect of shear deformations may produce greater inaccuracy than the neglect of creep.

One difficulty in including the effect of creep in a complicated structure is that at some points the stresses would be sufficient to cause creep but that at other locations (except on rare occasions) the stresses might be too light to cause creep. This would make the stresses due to creep discontinuous, whereas the elastic stresses would be continuous.

In two places the author indicates conceptions and conclusions that the writer considers to be erroneous—namely, the reference to end-moment distribution as "basic" in character and "fundamental" in nature, and the statement that it should be used for computing moments which include the effect of creep.

The basic constants of beam flexure for any beam are illustrated by Fig. 13 which shows the elastic curves, their tangents, and their long chords for the three different conditions that yield the basic constants of flexure. The illustrations can be considered as depicting railway curves or any geometrical curves, and the properties may be considered as geometrical rather than mechanical. The basic constants of flexure read from these figures are shown in Fig. 13. They are the best and the minimum number of constants necessary to determine the geometry of the triangles which circumscribe the elastic curves.

The end-moment distribution constants are not basic but are "derived" constants. For tapering members or other special conditions they become complex.

The writer would define a solution of basic character as one which uses the basic constants of flexure and which does not use any form of converging approximations. Such a solution is shown in Figs. 14 and 15. It involves fewer arithmetical operations than the author's solution. The arithmetic is simpler, in that there are no long columns of figures to add, and its result is more accurate than the author's. It will compute moments to any predetermined degree of accuracy in one operation. It does not involve the use of simultaneous equations. Except for the last operation, it has an automatic check by Maxwell's theorem of reciprocal deflections. The writer therefore contends that the author's statements regarding methods of computation are incorrect and that they tend to perpetuate a now common practice of failing to select the most effective method for analyzing a large class of structures.

JOSEPH MARIN,[30] ASSOC. M. AM. SOC. C. E.—The writer is greatly indebted to Professor Hrennikoff for pointing out two errors in this paper. With reference to the first one, it appears that the limitation in using only odd integer values for n is not a serious one. This fact is realized when the approximations involved in formulating a creep-stress law are considered and when the necessity of extrapolation is noted. If the test data on the material warrant a more accurate analysis than that indicated by the use of odd integers for n, it is always possible to solve the problem for two successive odd values of n and to interpolate for a particular value of n. Regarding the second error noted by Professor Hrennikoff, the writer realized that the law of superposition does not apply, and noted this in the paper (see heading, "Statically Indeterminate Structures: Example 5"). The general theory given in the paper ("Statically Indeterminate Structures: Moment-Distribution Method") appears to the writer to be correct. The application of this theory in Example 5 is incorrect as Professor Hrennikoff points out. That is, a new set of values for the carry-over and distribution factors should have been determined at each step in the moment-distribution procedure.

---

[30] Prof., Eng. Mechanics, Pennsylvania State College, State College, Pa.

The comments of Mr. Turner are of considerable interest and importance in the general problem of behavior of materials subjected to stresses. The validity of the assumption that plane sections remain plane is based on creep-deformation measurements made on beam specimens.[3]

The discussion by Mr. Stewart regarding the justification for considering creep and the difficulties encountered in applying creep-stress analysis to structures is significant. In many problems, creep may not be important, and in some cases it may be desirable to develop methods of analysis. The use of the words "basic" and "fundamental" seem to the writer questions of definition and point of view. However, the analysis given in Fig. 15 has considerable merit. This analysis, applied to the case of creep, gives similar results to Example 5 and is therefore incorrect.

PROFILE CURVES FOR OPEN-CHANNEL FLOW

By Dwight F. Gunder,[1] Esq.

With Discussion by Messrs. Carl Rohwer, C. J. Posey, J. C. Stevens, Boris A. Bakhmeteff and Nicholas V. Feodoroff, Hunter Rouse, and Dwight F. Gunder.

Synopsis

Certain irregularities appearing in the surface profile curves for gradually varied flow are discussed in this paper. These irregularities occur under conditions in which the depth of flow is less than both the normal and critical depths. Further, the equation of gradually varied flow in a wide rectangular channel is integrated for the case where the Chézy coefficient is given by the Manning relation $C = 1.486 \frac{R^{1/6}}{n}$. As a consequence of the contents of this paper, the curves for a variable Chézy coefficient given by the Manning relation are sketched, and it is concluded that:

(1) Perhaps the backwater curves in most texts are based on certain qualitative features of the equation of gradually varied flow, plus a knowledge on the part of the writers of what these curves should look like;

(2) The use of the differential equation of gradually varied flow at depths below both the critical and normal depths should be restricted, in that the Manning relation for the Chézy coefficient should not be used, although in most cases, from a theoretical standpoint, the Bazin or Ganguillet-Kutter relations are satisfactory; and

(3) The differential equation of gradually varied flow with the Chézy coefficient given by the Manning relation is integrated for the case of the broad rectangular channel.

***Notation.*—The letter symbols in this paper are defined where they first appear in the text and are assembled for convenience of reference in the Appendix.**

In calculating surface profile curves for gradually varied flow in open channels, using the customary step-by-step method in combination with the

---

Note.—Published in April, 1942, *Proceedings*.

[1] Research Engr. and Associate Prof., Math. and Civ. Eng., Colorado State College, Fort Collins, Colo.

differential equation of gradually varied flow, the writer found certain irregularities in the results. These irregularities consisted of deviations from the general shape for such curves as are found in the standard texts treating the subject of gradually varied flow. The deviations occurred in the case where the flow was at depths less than either the critical depth y_c or the normal depth y_o. (Hereafter, in this paper, curves satisfying these conditions of flow will be indicated by the subscript 3;[2,3] that is, in the case of a mild slope, $y_c < y_o$, that part of the profile of the surface of flow for depth less than y_c will be indicated by the symbol M_3.) A point of inflection appears in the calculated curves of this type (3), whereas such a point is not shown in the usual textbook graphs. Although not so stated in most of these texts, perhaps the surface profiles for gradually varied flow have been sketched from a combination of certain qualitative features of the equation, plus a knowledge of the forms which these curves should take. In this paper the usual differential equation will be re-derived, giving the result in a lucid form, and the correct profile curves corresponding to this equation will be drawn, assuming a Chézy coefficient varying according to the Manning, Bazin, or Ganguillet-Kutter relations. Further, the related academic problem of integrating the differential equation of gradually varied flow with a variable Chézy coefficient as given by the Manning relation will be solved for the case of a wide rectangular channel.

It is recalled that the general equation of varied flow is obtained as follows:[2] The mean total head E_w at a cross section is given by,

$$E_w = \frac{V^2}{2\,g} + y + h_o \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which V is the velocity of flow, g is the gravitation constant, y is the depth of flow, and h_o is the height of the bottom of the channel above an arbitrary horizontal datum. Differentiation of this equation with respect to x, the distance measured in the direction of flow, gives:

$$\frac{dE_w}{dx} = \frac{d}{dx}\left(\frac{V^2}{2\,g}\right) + \frac{dy}{dx} + \frac{dh_o}{dx} \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

In this equation the expression $\frac{dE_w}{dx}$, representing the rate of change of mean total head, is assumed to be the same as if the flow were uniform, and hence, by the Chézy relation, will be equal to $-\frac{V^2}{C^2\,R}$, C being the Chézy coefficient and R the hydraulic radius for the section of the channel under discussion. If b is the breadth, A the cross-section area, and Q the total discharge across the section of the channel, then the expression $\frac{d}{dx}\left(\frac{V^2}{2\,g}\right)$ can be modified by making $V = \dfrac{Q}{A}$ and noting that $dA = b\,dy$; whence,

[3] "Hydraulics of Open Channels," by Boris A. Bakhmeteff, McGraw-Hill Book Co., Inc., New York, N. Y., 1932 (see types 1 and 2).

$$\frac{d}{dx}\left(\frac{V^2}{2\,g}\right) = -\frac{Q^2\,b}{g\,A^3}\frac{dy}{dx} \qquad (3)$$

If S_o is the slope of the channel bottom (positive for a downward slope in the direction of flow), then $\dfrac{dh_o}{dx} = -S_o$, and Eq. 2 becomes,

$$-\frac{V^2}{C^2\,R} = -\frac{Q^2\,b}{A^3\,g}\frac{dy}{dx} + \frac{dy}{dx} - S_o \qquad (4)$$

or

$$\frac{dy}{dx} = \frac{S_o - \dfrac{V^2}{C^2\,R}}{1 - \dfrac{Q^2\,b}{A^3\,g}} \qquad (5)$$

Since in the remainder of this paper the writer is interested only in the case of the broad rectangular channel, the general Eq. 5 will now be simplified accordingly. It follows at once that for such a channel $R = y$, and that for a unit width of the channel $A = y$ (Q will be retained but is understood now to be the discharge per unit width of channel).

Remembering that the height H of the energy line above the channel bottom is given by $H = y + \dfrac{V^2}{2\,g}$, that $V = \dfrac{Q}{y}$, and that $\dfrac{dH}{dy}$ is equal to zero at the conditions of critical flow:

$$\frac{dH}{dy} = \frac{d}{dy}\left(y + \frac{Q^2}{2\,g\,y^2}\right) = 1 - \frac{Q^2}{g\,y^3} \qquad (6)$$

Hence, at critical conditions of flow,

$$y^3_c = \frac{Q^2}{g} \qquad (7)$$

y_c being the critical depth. This reduces the denominator of the right member of Eq. 5 to $1 - \dfrac{y^3_c}{y^3}$.

In a similar manner, by noting that at the normal depth y_o the energy loss $-\dfrac{dE_w}{dx} = -S_o$, it is seen that, for normal conditions of flow,

$$S_o = \frac{V^2}{C^2_o\,y_o} = \frac{Q^2}{C^2_o\,y^3_o} \qquad (8)$$

or

$$y^3_o = \frac{Q^2}{S_o\,C^2_o} \qquad (9)$$

in which C_o is the value of C when flow is at normal depth. Whence the numerator of Eq. 5 becomes:

$$S_o - \frac{V^2}{C^2 y} = S_o - \frac{Q^2}{C^2 y^3} = S_o - \frac{S_o C^2_o y^3_o}{C^2 y^3} = S_o \left(1 - \frac{C^2_o y^3_o}{C^2 y^3}\right) \ldots \text{(10)}$$

and Eq. 5 becomes:

$$\frac{dy}{dx} = \frac{S_o \left(1 - \dfrac{C^2_o y^3_o}{C^2 y^3}\right)}{1 - \dfrac{y^3_c}{y^3}} \ldots\ldots\ldots\ldots \text{(11}a\text{)}$$

In Eq. 11a the relation of the slope of the surface profile to the critical and normal depths appears in easily recognized form. This equation is valid when S_o is positive, negative, or zero. In the latter case, the equation simplifies to:

$$\frac{dy}{dx} = \frac{-g\, y^3_c}{C^2 (y^3 - y^3_c)} \ldots\ldots\ldots\ldots \text{(11}b\text{)}$$

The factor C may now be replaced by any one of the three expressions for it as given by Manning, Bazin, or Ganguillet-Kutter. For the moment the Manning relation

$$C = 1.486 \frac{R^{1/6}}{n} \ldots\ldots\ldots\ldots \text{(12)}$$

will be used. This value, when substituted in Eq. 11a, gives at once,

$$\frac{dy}{dx} = S_o \left[\frac{1 - \left(\dfrac{y_o}{y}\right)^{10/3}}{1 - \left(\dfrac{y_c}{y}\right)^3} \right] \ldots\ldots\ldots\ldots \text{(13)}$$

From Eq. 13 it is seen at once that the surface is vertical (a theoretical condition only, since the postulated uniform flow condition is not satisfied here) not only at the critical value but also at $y = 0$. Consequently, there must be a point of inflection in the type 3 curve (except when y_c is greater than, or equal to, y_o). To find the location of this point of inflection, Eq. 13 is differentiated with respect to x and the result is equated to zero. This gives:

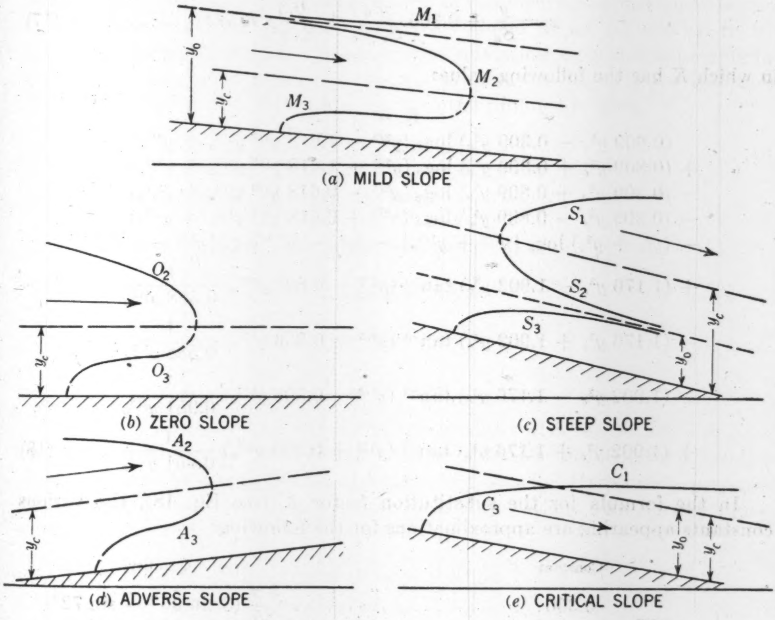
$$9\, y^3_c\, y^{10/3} - 10\, y^{10/3}_o\, y^3 + y^{10/3}_o\, y^3_c = 0 \ldots\ldots\ldots\ldots \text{(14)}$$

The solution of Eq. 14 for y is seen to depend upon both y_o and y_c. If y_c is much less than y_o, the resulting value of y is small and this point of inflection is near the bottom of the channel; but, if y_c approaches y_o, the value of y also approaches y_o. Even for the value $y_c = \frac{y_o}{2}$, the inflection occurs at about $y = \frac{y_o}{4}$.

However, if the value of C, as given by either the Bazin or Ganguillet-Kutter relations, is used in Eq. 11a, the inflection point, although still existing, is so close to the bottom of the channel that any error introduced by ignoring it is practically negligible. For the case of $y_c = \frac{y_o}{2}$, the point of inflection occurs at a value of y that is less than 1% of y_o. From the foregoing discussion two conclusions can be drawn at once:

(1) If step-by-step integration is used in the range of type 3 curves, the Chézy coefficient C should be determined by either the Bazin or Ganguillet-Kutter relation and not by the Manning relation; and

(2) Perhaps the backwater curves as drawn in the standard texts are based upon a constant Chézy coefficient C rather than upon one given by the usual Manning, Bazin, or Ganguillet-Kutter relations.[3a]



(*a*) MILD SLOPE

(*b*) ZERO SLOPE

(*c*) STEEP SLOPE

(*d*) ADVERSE SLOPE

(*e*) CRITICAL SLOPE

FIG. 1.—SURFACE PROFILES FOR GRADUALLY VARIED FLOW $C = 1.486 \frac{R^{1/6}}{n}$

In order to illustrate the contrast between the actual forms of the surface profiles for gradually varied flow in a broad rectangular channel, using a variable Chézy coefficient as determined by the Manning relation, and the forms of these profiles as sketched in texts for a constant Chézy coefficient, the sketches of the former curves are presented in Fig. 1 to be contrasted with the latter curves as found in textbooks.

[3a] See corrected conclusion in the closing discussion, p. 504.

The differential Eq. 13 is not difficult to integrate. In fact it may be rewritten in the form:

$$S_o\, dx = \frac{y^{1/3}\,(y^3 - y^3_c)\, dy}{y^{10/3} - y^{10/3}_o} \quad \dots\dots\dots\dots\dots\dots\dots (15)$$

or

$$S_o\,(x + C_1) = y + \int \frac{-\,y^{1/3}\, y^3_c + y^{10/3}_o}{y^{10/3} - y^{10/3}_o}\, dy$$

$$= y + \frac{1}{2\, y^{5/3}_o} \int \frac{-\,y^{1/3}\, y^3_c + y^{10/3}_o}{y^{5/3} - y^{5/3}_o}\, dy - \frac{1}{2\, y^{5/3}_o} \int \frac{-\,y^{1/3}\, y^3_c + y^{10/3}_o}{y^{5/3} - y^{5/3}_o}\, dy \quad \dots (16)$$

Although the details are somewhat tedious, each of these integrals can be evaluated by partial fractions. The result is:

$$x = \frac{y}{S_o} + 0.306\, \frac{y^3_c}{S_o\, y^2_o} + \frac{0.3}{S_o\, y^2_o}\, K \quad \dots\dots\dots\dots\dots (17)$$

in which K has the following value:

$$\begin{aligned} K = {} & \\ & (0.809\, y^3_c - 0.309\, y^3_o) \log_e (y^{2/3} - 1.618\, y^{1/3}\, y^{1/3}_o + y^{2/3}_o) \\ & + (0.809\, y^3_c + 0.309\, y^3_o) \log_e (y^{2/3} + 1.618\, y^{1/3}\, y^{1/3}_o + y^{2/3}_o) \\ & - (0.309\, y^3_c + 0.809\, y^3_o) \log_e (y^{2/3} - 0.618\, y^{1/3}\, y^{1/3}_o + y^{2/3}_o) \\ & - (0.309\, y^3_c - 0.809\, y^3_o) \log_e (y^{2/3} + 0.618\, y^{1/3}\, y^{1/3}_o + y^{2/3}_o) \\ & - (y^3_c + y^3_o) \log_e |y^{1/3} + y^{1/3}_o| - (y^3_c - y^3_o) \log_e |y^{1/3} - y^{1/3}_o| \\ & + (1.176\, y^3_c - 1.902\, y^3_o) \tan^{-1} (y^{1/3} - 0.809\, y^{1/3}_o)\, \frac{1}{0.588\, y^{1/3}_o} \\ & - (1.176\, y^3_c + 1.902\, y^3_o) \tan^{-1} (y^{1/3} + 0.809\, y^{1/3}_o)\, \frac{1}{0.588\, y^{1/3}_o} \\ & - (1.902\, y^3_c - 1.176\, y^3_o) \tan^{-1} (y^{1/3} - 0.309\, y^{1/3}_o)\, \frac{1}{0.951\, y^{1/3}_o} \\ & + (1.902\, y^3_c + 1.176\, y^3_o) \tan^{-1} (y^{1/3} + 0.309\, y^{1/3}_o)\, \frac{1}{0.951\, y^{1/3}_o} \quad \dots\dots (18) \end{aligned}$$

In the formula for the substitution factor K (see Eq. 18), the various constants appearing are approximations for the following:

Constant	Quantity
0.306	$\frac{3\pi}{25}$ (3 sin 36° − sin 72°)
0.809	cos 36°
0.309	cos 72°
1.618	2 cos 36°
0.618	2 cos 72°
1.176	2 sin 36°
1.902	2 sin 72°
0.588	sin 36°
0.951	sin 72°

All these constants arise from the integration and the determination of the constant of integration so that the origin will be at the intersection of the type 3 curve with the bottom of the channel. It is readily seen that several of the terms appearing in Eq. 18 could be combined; but the given form lends itself somewhat more readily to calculation. Furthermore, the logarithms have been left to the base e to facilitate work with the slide rule, by which satisfactory results can be obtained quite quickly.

The foregoing solution enables one to draw quantitative graphs of the various profile curves for the channel type considered here. Further, although it is not practical for accurate calculations of flow in natural stream beds, the equation is convenient for making rough approximations in such cases and for use in certain artificial stream beds. It is to be noted, of course, that this result, depending upon the Manning relation for C, is subject to the same restriction in the region of the type 3 curve as was mentioned previously herein.

The integration for zero and negative channel slopes is included in the integrated forms 17 and 18. However, the indeterminate forms appearing for the case of zero slope make it advisable to integrate Eq. 11*b* for this case. This integration is elementary and leads to the profile equation,

$$7.87\, g\, n^2\, y^3_c\, x = 13\, y^{4/3}\, y^3_c - 4\, y^{13/3} \quad \text{.............} (19)$$

in which n is the Manning roughness factor.

APPENDIX

NOTATION

The following letter symbols conform essentially with the Society's *Manual of Engineering Practice No. 11*, on "Letter Symbols and Glossary for Hydraulics," and American Standard Letter Symbols for Hydraulics, prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942:[4]

A = the area of the cross section of the flow;
b = the breadth of the channel;
C = the Chézy coefficient: C_o = the Chézy coefficient for normal depth of flow;
E_w = mean total head;
g = the gravitation constant;
H = the height of the specific energy line above the channel bottom;
h_o = the height of the channel bottom above an arbitrary horizontal datum;

---

[4] ASA—Z10.2—1942.

K = a simplifying, substitution factor (Eqs. 17 and 18);
M_3 = that part of the surface profile for a mild slope and depth of flow less than the critical depth;
n = Manning's roughness factor;
Q = total quantity of flow:
R = the hydraulic radius;
S_o = the slope of the channel bottom with respect to the horizontal;
V = the velocity of flow;
x = the distance measured parallel to the channel bottom;
y = the depth of the flow at any section:
  y_c = the depth of flow for critical flow conditions; and
  y_o = the normal depth of flow.

DISCUSSION

Carl Rohwer,[5] **Assoc. M. Am. Soc. C. E.**—There is considerable difference between the shape of certain types of profile curves as generally shown in textbooks and the shape obtained by the solution of the backwater formula. This is demonstrated clearly by Professor Gunder. The question immediately arises as to which of these is the true shape of the profile in a stream or canal under the conditions producing this type of backwater curve. Obviously, both cannot be correct. If there is a point of inflection in the curves, as stated by the author, then the curvature will change from concave upward to concave downward and the length of the surface profile would be materially reduced, in consequence. If this change in the shape of the profile actually occurs in nature, it is strange that this fact has not been revealed before. Such a change scarcely could have passed unnoticed by engineers taking levels on profiles under the conditions necessary to produce this phenomenon. It seems more plausible to the writer that this discrepancy is caused by some error in the assumptions involved in the derivation of the backwater equations rather than in the failure to observe the physical facts. The discovery of this anomaly in the general equation of surface profiles leads one to wonder if the application of the equation to the solution of the shapes of other types of profile curves may not result in errors that are not so readily detected.

Although the study of surface profiles in open channels for gradually varied flow is of special interest to engineers concerned with the problem of determining the rise in the water level in streams above dams and locks, it is of importance, also, to engineers engaged in the design of irrigation structures. The writer's experience is limited to the special backwater curve produced when a Parshall flume[6] is installed in a canal. Since the Parshall flume constricts the channel, there is an increase in the depth of the canal above the flume. The amount of this increase has been determined by tests on flumes of various sizes for a wide range of discharges. This increase in depth extends upstream in the canal and, since the head gate and diversion dam are usually only a short distance from the Parshall flume, the problem is to determine whether the rise in the canal will be sufficient to make it necessary to increase the height of the diversion dam.

Canal cross sections are relatively narrow and deep; consequently, it cannot be assumed that the hydraulic radius is equivalent to the depth. To determine the effect of backwater, it is therefore necessary to divide the canal into sections for which the length, corresponding to an arbitrarily chosen change in depth, can be computed. This is a tedious process. It is hoped that the author will derive a simple equation, applicable to the surface profile produced in this special case.

C. J. Posey,[7] **Assoc. M. Am. Soc. C. E.**—Upon reading this paper, one wavers between two conclusions—that Professor Gunder is wrong, or that the backwater curves shown in standard texts are seriously in error. Fortunately, neither conclusion is correct. The principal difference lies in the shape of the type 3 curves in channels of mild, zero, adverse, or critical slope. According to Fig. 1, the M_3, O_3, and A_3 curves start perpendicular to the bottom of the channel and are concave downward for some distance before becoming concave upward. Previously published sketches of these curves have shown them as concave upward from end to end. The C_3 curve in Fig. 1 starts upward perpendicular to the bottom and is concave downward all the way to the critical depth line. Heretofore it has been shown as a simple horizontal line.

Actually, the discrepancies are not as serious as one might infer from examination of Fig. 1. The author himself states that the point of inflection lies near the bottom of the channel—very close to it if the Bazin or Ganguillet-Kutter expressions are used for the Chézy coefficient. Even if the Manning relationship is used the discrepancies are not important. In drawing small-scale illustrations such as Fig. 1, the true shape of the curves often must be modified. That Fig. 1 has been somewhat distorted is shown by the fact that the curves start up from the bottom at right angles to it, whereas, according to the text of the paper, they should start up vertically. This peculiar feature of the curves, which is the most surprising result of Professor Gunder's studies, and which makes the reversal of curvature necessary, can easily be shown to be consistent with the assumptions ordinarily made in computing backwater curves.

The rate of loss of head through friction, with respect to distance along the channel, is assumed to be given by Chézy's formula

$$S_f = \frac{Q^2}{C^2\, y^3} \qquad (20)$$

In the range of infinitesimal depths close to the bottom of the channel the velocity head is very great, and changes at a rapid rate, whereas the elevation head is scarcely changing at all. In a rectangular channel the rate of change of velocity head, with respect to distance along the channel, is given by

$$\frac{d}{dx}\left(\frac{V^2}{2\,g}\right) = \frac{d}{dx}\left(\frac{Q^2}{2\,g\,y^2}\right) = -\frac{Q^2}{g\,y^3}\frac{dy}{dx} \qquad (21)$$

Since the change of elevation head is comparatively insignificant, the friction loss is derived almost entirely from the change of velocity head. Equating the values given by Eqs. 20 and 21, and changing signs to allow for the implicit negative sign of S_f, one finds that for depths close to zero

$$\frac{dy}{dx} = \frac{g}{C^2} \qquad (22)$$

From this expression it is evident that if any formula is used in which C approaches zero as y approaches zero, the corresponding water-surface slope will be infinite. The limit is entirely theoretical, of course, representing a flow condition impossible of attainment.

The evaluation of friction in the region near this limit, where the velocity of flow is many times the Belanger critical, is very uncertain. It is customary to assume that the rate of loss of head by friction, in variable flow, is the same as in uniform flow at the same depth and velocity. The rate of loss in uniform flow is then computed by one of the standard open-channel formulas. It is doubtful, however, whether any open-channel formula has a proven range extending to velocities greater than twice the critical. Observations of extremely high velocities are difficult, and flow on slopes steep enough to sustain such velocities is almost certain to become pulsating or "slug" flow rather than uniform flow.[8] Although uniform flow at the high velocities existing in the lower portions of the type 3 curves is nearly impossible, variable flow in this range can exist. Examples of computed profiles for a common case are shown in Fig. 2. A discharge of 507 cu ft per sec flows out from under a gate into a channel with horizontal bottom. Flow is from left to right in the figure, and two possible conditions of flow starting from different gate heights are shown. The Manning formula is used, with *n* taken as 0.016. If the bottom of the gate is 10 ft above the horizontal bottom of the channel, the water is backed up to a depth of 50 ft behind the gate. If the bottom of the gate is 4 ft above the bottom of the channel, the depth upstream becomes 254 ft. In either case the water-surface profile computed by Eq. 19 follows the same curve, crossing the critical depth vertically at a point 3,370 ft downstream from the gate when the opening is 10 ft, or 6,250 ft downstream when the opening is 4 ft.

FIG. 2.—WATER-SURFACE PROFILES OF THE O_3 TYPE, BASED ON VARIABLE OR CONSTANT CHÉZY COEFFICIENTS

Water-surface profiles computed using the constant value of *C* which corresponds to the median value of *y* are also shown in Fig. 2. The curve downstream from the 10-ft gate reaches the critical depth in a distance of 3,500 ft, 4% in excess of the value given by Eq. 19. The curve starting at the 4-ft gate reaches the critical depth 6,760 ft downstream, a distance 7½% greater than that given by Eq. 19. Although it is evident that the discrepancy would be greater for smaller gate openings, the 4-ft gate opening is already beyond the range of values likely to be encountered in practice. The discrepancies could be decreased by using a value of C corresponding to an estimated average value of y rather than the median value. For example, with the gate at 10 ft, a value of C corresponding to a depth of 13 ft gives a result differing from that computed by Eq. 19 by less than 1%.

---

[8] "A Criterion for Instability of Flow in Steep Channels," by G. H. Keulegan and G. W. Patterson, *Transactions*, Am. Geophysical Union, 1940, Pt. II, p. 594.

With regard to simplicity, it is not much easier to use a constant value of C in computing the O_3 curves than to use Eq. 19, but the use of a constant value of C in computing M_3 and A_3 curves permits the use of Bresse's function,[9] with great saving in labor over that required in using Eqs. 17 and 18.

From a practical viewpoint, there seems to be little choice between results obtained using a variable Chézy coefficient and those obtained using a constant coefficient. The effect of channel shape will ordinarily be of greater importance. Until a comparison has been made with data from variable high-velocity flow in wide rectangular channels, neither method can be considered to have superior accuracy. The author's prediction of a reversal of curvature in the type 3 curves, a phenomenon which may be observable in channels of any shape, should help to stimulate interest in obtaining actual measurements.

J. C. STEVENS,[10] M. AM. SOC. C. E.—When the writer began reading Professor Gunder's paper, he thought: "Here's just what we've been looking for"; and, when he had read as far as his general differential equation for the surface profile (Eq. 13), it appeared so innocent that he thought: "We'd better turn real mathematicians loose on some of our other problems." Then, on turning the page, that innocent looking thing the Professor states "is not difficult to integrate" loomed out of the darkness like the iceberg did to the *Titanic* and wrecked everything. It is suggested that the Professor be sentenced to prepare a table of values of his K-factor, in terms of y, y_c, and y_o, varying by tenths of feet to 50 ft. One wonders how large a volume it would make.

However, it does prove that, defining the friction factor by the Manning relation (which is purely empirical and dimensionally incorrect), the surface profiles, determined for a unit width of a wide channel (which does not exist), contain points of inflection in the range where depths are less than either normal or critical, in which range the Manning formula does not apply! Professor Gunder did quite well with his disclaimers, but he is challenged to beat that one.

After all, it appears as though hydraulic engineers will just have to struggle along with their old step-by-step method of computing water-surface profiles.

BORIS A. BAKHMETEFF,[11] M. AM. SOC. C. E., AND NICHOLAS V. FEODOROFF,[12] ESQ.—A serious error that has remained unnoticed in hydraulic literature for years has been disclosed by Professor Gunder. As correctly surmised by the author, the shape of the so-called M_3 surface curve, traditionally presented in textbooks, dates back to the past century, when varied flow profiles were first classified by considering the special case of broad rectilinear channels, with the further simplifying premise of a constant average Chézy factor C applied over the entire range of depths. Under these special conditions, the outline of the M_3-curve remains concave $\left(\frac{dy}{dx} > 0; \frac{d^2y}{dx^2} < 0\right)$ for all the depths, tending toward $\frac{dy}{dx} = \infty$ as y approaches the critical value. A further circumstance to be taken into account is that within the customary reaches the M_3-profiles happen to be very "flat," exhibiting (except near y_c) only slight curvature and, on the whole, approximating a straight line. This means that the changes in curvature, as disclosed by Professor Gunder, were not conspicuous and the observed appearances did not upset accepted notions. Therefore, the over-all concave M_3-profile, initially deducted for specific conditions, was inadvertently extended and assumed to apply in all cases, without due investigation of the special effects devolving from a variable friction factor. For such unpardonable negligence, the senior writer, as the author of a manual especially devoted to varied flow, presents his humble apologies. It should be stated, nevertheless, that at least in some texts[13] the tracings of the M_3-curve in the conventional surface profile diagrams are "stopped" at a certain distance from the bottom, indicating that in the vicinity of $y = 0$ the deductions drawn from the general varied flow equation cannot apply.

---

[9] Tables of Bresse's function for adverse as well as mild and steep slopes are given in "Hydraulics of Steady Flow in Open Channels," by Sherman M. Woodward and Chesley J. Posey, John Wiley & Sons, New York, N. Y., 1941.

[12] Research Associate, Civ. Eng. Dept., Columbia Univ., New York, N. Y.

Professor Gunder refers to the features disclosed by him as "irregularities." It is only proper to qualify previous ideas as plainly erroneous, and to accept the author's discoveries as regular characteristics of the M_3 varied flow curves, especially as these properties seem to have a broader significance than that suggested by the paper, and as they will be found to obtain quite generally, irrespective of the particular formula used for the C-factor.

The following analysis complements Professor Gunder's pioneer findings, which from now on should replace all former ideas relating to M_3-curves. Also, his discoveries are interpreted in the light of experimental evidence.

(1) The first deduction, drawn by Professor Gunder from Eq. 13, is that the surface curve for broad rectilinear channels with Manning coefficients theoretically becomes vertical at $y = 0$. As a matter of fact, this property is not to be limited to any particular form of channel or to any specific friction formula. Indeed, it constitutes a general characteristic which applies in all instances. In the general varied flow equation[14]

$$\frac{dy}{dx} = S_o \frac{1 - \dfrac{A^2_o\, R_o\, C^2_o}{A^2\, R\, C^2}}{1 - \dfrac{Q^2\, b}{g\, A^3}} \qquad \ldots\ldots\ldots\ldots\ldots (23)$$

when the depth approaches zero, the unity factors both in the numerator and denominator become small by comparison to the second members, and can be omitted. Accordingly, with $S_o\, A_o\, R_o\, C_o = Q$, the limit of the surface gradient

---

[13] "Hydraulics of Open Channels," by Boris A. Bakhmeteff, McGraw-Hill Book Co., Inc., New York, N. Y., 1932, p. 76.

[14] *Ibid.*, Eq. 21, p. 31.

$$\text{Limit}\left(\frac{dy}{dx}\right)_{y\to 0} = \frac{\dfrac{Q^2}{A^2\,R\,C^2}}{\dfrac{Q^2\,b}{g\,A^3}} = \frac{g}{C^2}\,\frac{p}{b} = \sigma \ldots\ldots\ldots\ldots (24)$$

in which σ is the critical slope.[15] For small depths, $\frac{p}{b}$ tends toward unity. Hence,

$$\text{Limit}\left(\frac{dy}{dx}\right)_{y\to 0} = \frac{g}{C^2} = \frac{c_f}{2} \ldots\ldots\ldots\ldots (25)$$

in which c_f is the dimensionless friction drag coefficient in the average wall stress expression

$$\tau_o = \rho\, c_f\, \frac{V^2}{2} \ldots\ldots\ldots\ldots (26)$$

By reason of its physical essence, as well as theoretically in the customary Bazin, Ganguillet-Kutter, Manning, etc., relations, the C-factor for $y \to 0$ tends to become zero, making the critical slope $\left(\text{and thus } \frac{dy}{dx} \text{ in Eq. 25}\right)$ infinite. Note that this feature does not depend on the value of the channel slope S_o. In other words, all surface curves, both of the M_3 and the S_3 class, tend to be theoretically vertical at $y = 0$.

(2) As Professor Gunder infers, properties derived from the $y \to 0$ region represent purely theoretical conditions. The important practical effect, nevertheless, is that in the reach of small depths the M_3-curve must be convex $\left(\frac{d^2y}{dx^2} < 0\right)$, and that therefore at some depth y_i, between $y = 0$ and $y = y_c$, there is an inflection of curvature, with the surface profile changing from convex to concave. The paper conveys the impression that the eventual location of y_i is particularly affected by friction coefficients expressed through the Manning formula. In fact, the paper suggests (line 12 following Eq. 14) that "* * * in the range of type 3 curves, the Chézy coefficient C should be determined either by the Bazin or Ganguillet-Kutter relation and not by the Manning relation." The recommendation apparently is actuated by the desire to avoid the noted "irregularities."

One should not try to escape facts. What really matters is whether the property in question is actual or not; and under all circumstances the selected formula should be the one that is known to comply best with established reality. Unfortunately, very little is known about resistances in rapid (shooting) motion. In such a region investigators use formulas and coefficients deduced from observations in tranquil motion ($y > y_c$) without any direct assurance that they apply equally to supercritical ($V > V_c$) flow. Moreover, for "slowly varied (parallel) motion,"[16] they assume that the friction rate for a certain discharge and depth is substantially equal to what the resistance would have been under uniform conditions. In the M_3-case, flow is divergent and the divergence at times becomes quite pronounced. Analogous to closed conduits, one may anticipate a complementary loss connected with the restoration of kinetic energy into potential energy. Again, there is no material available at present that would evidence the magnitude of such restoration losses in open-channel flow.

---

[15] "Hydraulics of Open Channels," by Boris A. Bakhmeteff, McGraw-Hill Book Co., Inc., New York, N. Y., 1932, p. 48.

[16] *Ibid.*, pp. 8, 24, and 29.

Accordingly, in many respects the precise answers to the questions raised by the paper will have to await evidence from future research. In the meantime, one is forced to seek approximate solutions by recourse to one or another of the existing friction formulas, and it is here that the writers cannot quite follow Professor Gunder's conclusions, for their investigations seem to show that the choice of any relation for C does not materially affect the position of the inflection point.

(3) The location of the "inflection depth" y_i on the M_3-curve, where the curvature changes from convex to concave, can be expressed conveniently in dimensionless terms by the ratio

$$\frac{y_i}{y_c} = \frac{\text{inflection depth}}{\text{critical depth}} = (y'_c)_i \dots\dots\dots\dots\dots\dots (27)$$

Generally, the y_i-value will be influenced by the shape of the channel, the discharge, the slope S_o, and the wall roughness. For two-dimensional motion (broad, rectangular channel), the shaping agencies are reduced to the parametric ratio

$$\frac{y_c}{y_o} = \frac{\text{critical depth}}{\text{normal depth}} = \eta_c \dots\dots\dots\dots\dots\dots (28)$$

and to the form of the function

$$C = f(y) \dots\dots\dots\dots\dots\dots\dots\dots (29)$$

which depicts the change of the Chézy factor C with the varying depth of flow.

To apprehend the possible effect of the different formulas for C, it is necessary to make clear the physics that actually underlie the structure of all empirical relations. In all formulas, a "surface roughness type" is characterized by a proper numerical term, such as the n-factor in the Ganguillet-Kutter and the Manning expressions. Such a friction term is held to be invariant for all conduits involving a particular type of surface roughness. Each formula offers the friction term with a mathematical expression deemed to represent best the factual change of C with the conduit size. In all instances C increases with the latter, the implied physical meaning being that the friction term n exemplifies a certain roughness size, and that the increase of C with the hydraulic radius R reflects the eventual reduction of the friction drag with the decrease of the relative roughness. In fact, relative roughness appears in the empirical relations in the form of a ratio of the friction term to an appropriate power of the hydraulic radius. Thus, the Bazin and Kutter expressions are built around the ratio of the friction term to $\sqrt{R}$, whereas in the Manning formula the shaping ratio is $\frac{n}{R^{1/6}}$. In general, the aim of "empirical" research in the past was to evolve a mathematical form between C and R, which for a certain "n" would best average and fit the maze of observational data assumed to respond to the same roughness type. In essence, the purpose was essentially the same, as answered more recently by the Prandtl-Kármán semi-rational theory, which expressed the interrelation between $\frac{1}{\sqrt{c_f}} = \frac{C}{\sqrt{2\,g}}$ and the relative roughness $\frac{e}{R}$ in logarithmic terms.

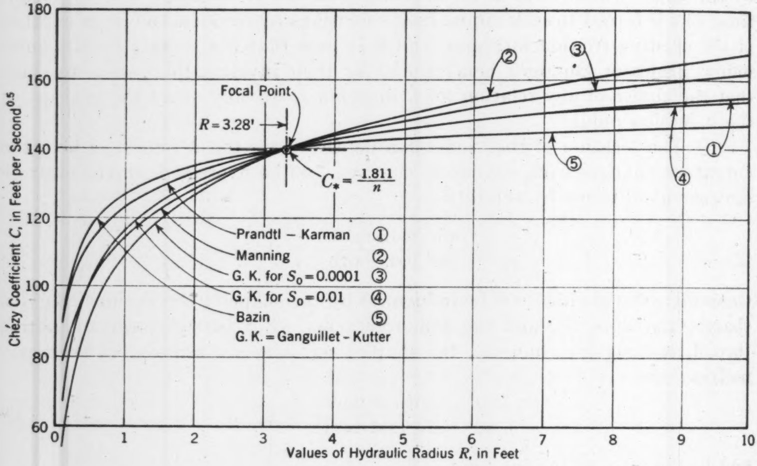

FIG. 3

A comparison of the different suggestions is given in Fig. 3, which shows a group of $C = f(R)$-curves computed by the different formulas with the Ganguillet-Kutter term $n = 0.013$. It should be remembered that, in the otherwise rather complex and obviously artificial Ganguillet-Kutter structure, the value of C_*, for $R = 3.28\text{ ft} = 1\text{ m}$, constitutes a focal point at which the Chézy factor is assumed to be unaffected by the slope S_o, and in metric measures is numerically equal to $C_* = \frac{1}{n}$. For feet, the focal value is $C_* = \frac{1}{n}\sqrt{3.28} = \frac{1.811}{n}$. It is the same focal point that conditions the Manning curve, the metric form for which is

$$C = C_*\,R^{1/6} = \left(\frac{1}{n}\right) R^{1/6} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (30a)$$

which is expressed in feet as

$$C = \left(\frac{1.811}{n}\right)\left(\frac{R}{3.28}\right)^{1/6} = \left(\frac{1.49}{n}\right) R^{1/6} \ldots\ldots\ldots\ldots (30b)$$

On the other hand, the logarithmic expression

$$C = (C_* - 16.5) + 32.1 \log R = \frac{1.811}{n} - 16.5 + 32.1 \log R \ldots (31)$$

represents, in foot units, the Prandtl-Kármán curve, customarily referred to as the Nikuradze formula, adapted to pass through the Ganguillet-Kutter focal point for the roughness term n. (In the well-known expression for rough pipes,

$$1 \sqrt{f} = A_r + 2 \log \frac{r_o}{e} \ldots\ldots\ldots\ldots (32)$$

replace $\frac{1}{\sqrt{f}} = \frac{1}{\sqrt{4\,c_f}}$ by $\frac{C}{\sqrt{8\,g}}$, and r_o by 2 R. This gives

$$C = \sqrt{8\,g}\left(A_r + 2 \log \frac{2}{e}\right) + 2\sqrt{8\,g} \log R \ldots\ldots (33a)$$

or, in foot units,

$$C = A_c + 32.1 \log R \ldots\ldots\ldots\ldots (33b)$$

For R = 3.28 ft, C must equal $C_* = \frac{1.811}{n}$. Hence, the constant $A_c = C_* - 32.1 \log 3.28 = \frac{1.811}{n} - 16.5$.) Finally, the Bazin curve $C = \frac{158}{1 + \frac{M}{\sqrt{R}}}$ is fitted to pass through the focal point by making the friction term $M = 158\,n - 1.811$.

In Fig. 4 the C-values are plotted logarithmically. As seen, the curvature of the outlines becomes rather unpronounced, and one is naturally tempted, for example, to replace the complex Ganguillet-Kutter relation by a suitable straight line answering the exponential relation $C = C_* R^p$, passing through the focal point C_*, and adjusted, so far as the incline p is concerned, to approximate best the $C = f(R)$-curve in the desired region. This explains the origin and the significance of the Manning formula, which is fitted to conform with $p = \frac{1}{6}$.

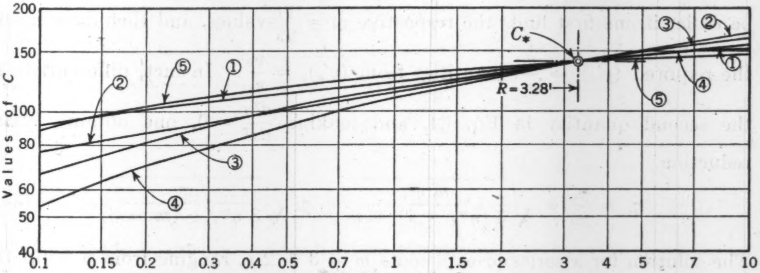

FIG. 4

More generally, in the light of Fig. 4, one may state that the various relations of C versus R differ by the relative steepness of their incline. Therefore, if an exponential expression were to be used for approximating the $C = f(R)$-function in that or any other reach of the curve, the respective formulas could be said to differ by a larger or smaller value of the exponent. The particular effect on Eq. 23 would be the substitution, in the numerator, of the ratio $\left(\frac{R_o}{R}\right)^{2p}$ for $\left(\frac{C_o}{C}\right)^2$.

(4) In the particular instance of a broad rectangular channel (Eq. 11*a*), one obtains, with such substitution,

$$\frac{dy}{dx} = S_o \frac{1 - \left(\frac{y_o}{y}\right)^{3+2p}}{1 - \left(\frac{y_c}{y}\right)^3} = S_o \frac{1 - \left(\frac{y_o}{y}\right)^m}{1 - \left(\frac{y_c}{y_o}\right)^3 \left(\frac{y_o}{y}\right)^3}$$

$$= S_o \frac{1 - \left(\frac{y_o}{y_c}\right)^m \left(\frac{y_c}{y}\right)^m}{1 - \left(\frac{y_c}{y}\right)^3} \dots\dots\dots\dots\dots\dots (34)$$

The possible influence of friction, as appraised by different formulas, depends on determining the value of $(y'_c)_i = \frac{y_i}{y_c}$, which in Eq. 34 would correspond to the different values of the "hydraulic exponent," $m = 3 + 2p$, subject to the parametric values of $\eta_c = \frac{y_c}{y_o}$. One could proceed directly by using the third quantity in Eq. 34; but the numerical computations prove to be easier if one first finds the respective $\eta_i = \frac{y_i}{y_o}$-values, and then determines the required $(y'_c)_i = \frac{y_i}{y_c}$-quantities from $(y'_c)_i = \frac{\eta_i}{\eta_c}$. In fact, differentiating the second quantity in Eq. 34, and making $\frac{d^2y}{dx^2} = 0$, one obtains, after reduction,

$$\eta_c = \frac{y_c}{y_o} = \sqrt[3]{\frac{m\,\eta^3_i}{3\,(\eta^m_i - 1) + m}} = \eta_i \sqrt[3]{\frac{m}{3\,\eta^m_i + (m - 3)}} \dots\dots (35)$$

The solution for a series of exponents $m = 3 + 2p$, ranging from $p = 0.1$ to $p = 0.4$, thus embracing all the possible slopes in Fig. 4, is presented in Fig. 5(*a*). Fig. 5(*b*) shows the final values of $(y'_c)_i = \frac{y_i}{y_c}$ versus $\eta_c = \frac{y_c}{y_o}$. In particular, the values of $(y'_c)_i$ for the vertical $\eta_c = 0$, which corresponds to flow over a horizontal bed, are found from Eq. 11*b*:

$$\frac{dy}{dx} = -\frac{g\,y^3_c}{C^2\,y^3\left(1 - \frac{y^3_c}{y^3}\right)} = -\frac{g\,y^3_c}{C^2_*\,y^m\left(1 - \frac{y^3_c}{y^3}\right)} \dots\dots\dots (36)$$

which, when differentiated and solved for $\frac{d^2y}{dx^2} = 0$, gives

$$(y'_c)_i = \left(\frac{y_i}{y_c}\right)_{S_o=0} = \sqrt[3]{\frac{m-3}{3}} \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

As seen, the $(y'_c)_i$ versus η_c outline is rather flat, except when η_c approaches unity—that is, when the slope S_o becomes close to the critical, and the normal depth tends to become critical. Therefore, under ordinary circumstances, for $y_c \lesssim 0.6\, y_o$, the simpler expression (Eq. 37) can be conveniently used for quick appraisals. On the other hand, for all possible values of the exponent, the inflection depth y_i remains within 0.4 to 0.6 of the critical, showing remarkable steadiness in its position. Thus, a rule of thumb, assuming inflection at about half the critical depth, seems to be a justifiable approximation.

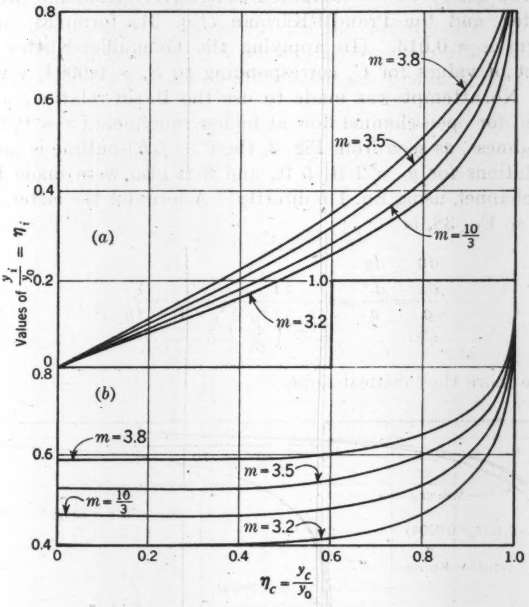

FIG. 5

(5) The purpose now is to disclose in a more direct fashion the exact possible effect of that or some other friction formula. Also, in view of the "flatness" of the M_3-curves, it is desirable to know more about their eventual outline in the regions adjoining the inflection point. The general procedure would be cumbersome and ineffective, so recourse must be had to practical examples. Calculations were performed for a wide range of circumstances, assuming two-dimensional flow at $y_o = 10$ ft, and making y_c successively 2 ft,

5 ft, and 8 ft. Using Eq. 11*a* in the form

$$\frac{\frac{dy}{dx}}{S_o} = \frac{1 - \left(\frac{C_o}{C}\right)^2 \left(\frac{y_o}{y_c}\right)^3 \left(\frac{y_c}{y}\right)^3}{1 - \left(\frac{y_c}{y}\right)^3} \qquad (38)$$

one determined the dimensionless ratio $\left(\frac{dy}{dx}\right): S_o$ versus $y'_c = \frac{y}{y_c}$, with the values for the Chézy factor computed successively from the Manning, Ganguillet-Kutter, and the Prandtl-Kármán (Eq. 31) formulas, and with the friction term $n = 0.013$. (In applying the Ganguillet-Kutter formula, an identical set of values for C, corresponding to $S_o = 0.0004$, was used in all instances. No attempt was made to use the Bazin relation. The latter is well adapted for open-channel flow at higher roughness [$n = 0.020$ to 0.025]. At low roughness, as seen from Fig. 3, the $C = f(R)$-outline is much too flat.)

Computations for $y_c = 2$ ft, 5 ft, and 8 ft also were made for flow in a horizontal channel, using Eq. 11*b* directly. A form for the latter, which would correspond to Eq. 38, is

$$\frac{\frac{dy}{dx}}{\frac{g}{C^2}} = \frac{\frac{dy}{dx}}{\sigma} = \frac{1}{1 - \left(\frac{y}{y_c}\right)^3} = \frac{1}{1 - (y'_c)^3} \qquad (39)$$

with σ once more the "critical slope."

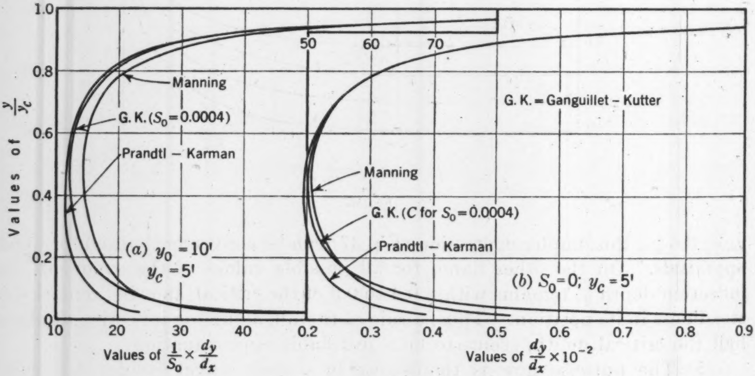

FIG. 6

Curves for the case of $y_c = 5$ ft are presented in Fig. 6. The outlines as shown are typical of the plottings obtained in all instances. All the $\frac{dy}{dx}$-curves exhibit only slight change over a comparatively wide middle reach, revealing the previously emphasized flatness of the M_3-curve. The curvature as derived from Eqs. 38 and 39 becomes pronounced only near $y = y_c$, and close to the bottom, where the computations based on the Bélanger premises of parallel motion with negligible curvature cease to be applicable. Again the curves corresponding to the different formulas vary only in detail, without changing the major features of the picture.

(6) It behooves one now to compare the results of the theoretical computations with actual observations. In practice, M_3 surface curves occur at the foot of spillways and chutes, where the steep incline changes to a mild slope channel, or at the point where water flows from beneath a sluice into a horizontal or mildly sloped bed. In either case the initial surface, in the transition reach, is ipso facto concave. Accordingly, if the initial depth is less than y_c, the subsequent flow must exhibit a portion of convex surface between two concave reaches. Such a succession of forms in practice is highly improbable.

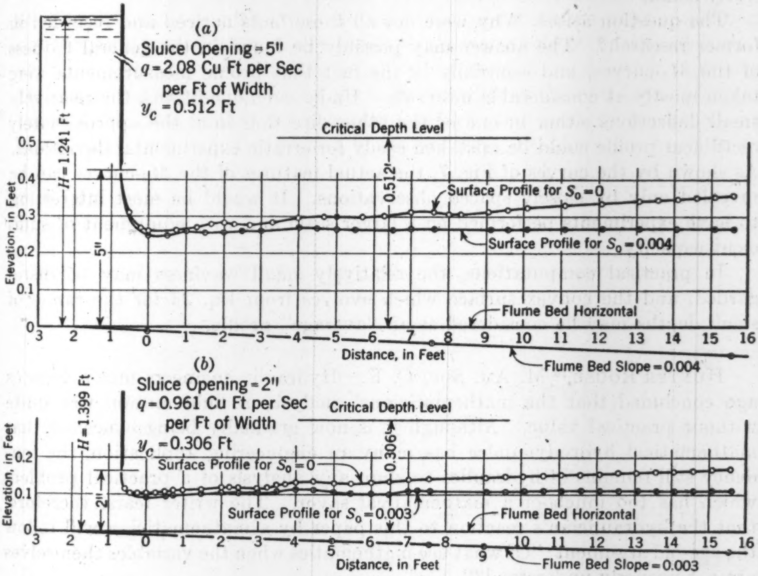

FIG. 7

Moreover, whenever, in hydraulics, a certain equation results in two distinct branches, as in Eqs. 38 and 39 in Fig. 6, one is certain to anticipate that the respective branches reflect altogether different physical regimen, or that flow on one of the branches is unstable and in reality presents wavy features. An example is the double-branched curve[17] which features the height of the jump sustained by flow from under a sluice, and in which the branch for lower initial kinetic energies corresponds to jumps of the "undular" type. Thus, with respect to the M_3-curves (Fig. 6), one could reasonably expect that the lower and theoretically convex part of the profile will prove in reality to be more or less undulated. Special experiments in the 6-in. tilting flume of the Fluid Mechanics Laboratory of Columbia University in New York, N. Y., confirm such anticipation. The profiles shown in Fig. 7 are typical of the results obtained for a wider range of sluice openings and initial heads. In each instance, the surface profile in the reach succeeding the initial "contracted" section exhibits distinct undular outlines. The waves are not large, however, and furthermore their size decreases with the increase of the depth, as the curve evolves into the final, practically linear, form. Most characteristically, the effect of waviness was particularly accentuated in the bottom pressures. Apparently, due to the high prevailing velocities, substantial centrifugal effects were exercised even when the curvature, caused by the waves, was comparatively small.

---

[17] "Hydraulics of Open Channels," by Boris A. Bakhmeteff, McGraw-Hill Book Co., Inc., New York, N. Y., 1932, p. 248.

The question arises: Why were not all these facts noticed and recorded in former research? The answer may possibly be found in the general flatness of the M_3-curves, and especially in the fact that profile measurements were taken mostly at considerable intervals. Under such conditions, the relatively small deflections either in one or the other direction from the approximately rectilinear profile could be mistaken easily for erratic experimental deviations. As shown by the curves of Fig. 7, the actual features of the M_3-curves can be revealed only by closely spaced observations. It would be most interesting to have experiments performed on a larger scale and with equipment of sufficient capacity.

In practical computations, the relatively small waviness may be disregarded, and the convex surface which evolves from Eq. 23 for the range of small depths may be considered as an "average" profile.

HUNTER ROUSE,[18] M. AM. SOC. C. E.—Hydraulic engineers many decades ago concluded that the mathematicians' analysis of fluid motion was quite without practical value. Although it is now gradually being conceded that mathematical hydrodynamics has many an engineering application, the tendency still remains in hydraulics to shun any analysis of a practical problem which has too much of a mathematical savor. The writer fears, therefore, that the hydraulician's reaction to this paper by a mathematician will follow the age-old argument: "Of what use mathematics when the variables themselves are not properly understood?"

The writer feels responsible to some extent for Professor Gunder's attack upon this problem, for it was during the writer's lectures on advanced fluid mechanics at Fort Collins, Colo., in July, 1940, that the author clarified the consistent failure of computed surface curves below the critical depth to agree with the traditional curves in the writer's text. Comments by the writer on the obvious difficulty of integrating the varied-flow equations then led Professor Gunder to perform this integration, largely to satisfy his own curiosity. The results were finally submitted to the Society, not—so far as the writer is aware—

---

[18] Prof., Fluid Mechanics, State Univ. of Iowa, and Assoc. Dir. in Charge of Laboratory, Iowa Inst. of Hydr. Research, Iowa City, Iowa.

in the guise of a final solution to the varied-flow problem, but simply to place on record the information contained therein.

It is scarcely to be expected, of course, that a member of one profession should at once feel as much at home in another profession as in his own. It is the writer's experience, however, that mathematicians have far greater facility in grasping the salient features of an engineering problem than have engineers in mastering the mathematics necessary to its solution. For this reason, the writer most cordially welcomes Professor Gunder's initial contribution to the hydraulic engineering field, regardless of the merit of the paper itself. This profession, as already stated, still suffers from many misunderstandings of the past century, and can only profit from a mathematician's ability to cope with functional relationships which are beyond the normal engineering grasp.

As to the actual merits of this paper, the writer believes that the conclusions would be far more significant if freed from the handicap of being based upon resistance formulas which are in themselves none too trustworthy. Although the Manning formula is not necessarily worse than those of Bazin and Kutter, as implied by the author in his second conclusion, it is obviously more convenient than the other two, else the author would not have chosen it for purposes of integration; that it yields results which differ from those of the other two is surely not sufficient reason to condemn it. On the other hand, it has been shown both experimentally and analytically that the actual resistance due to wall roughness varies with the logarithm, rather than some power, of the relative roughness. Since logarithmic and power functions can approximately coincide over only a limited range, the author's curves necessarily reflect the discrepancies to an ever-increasing degree as they approach an upper or lower limit.

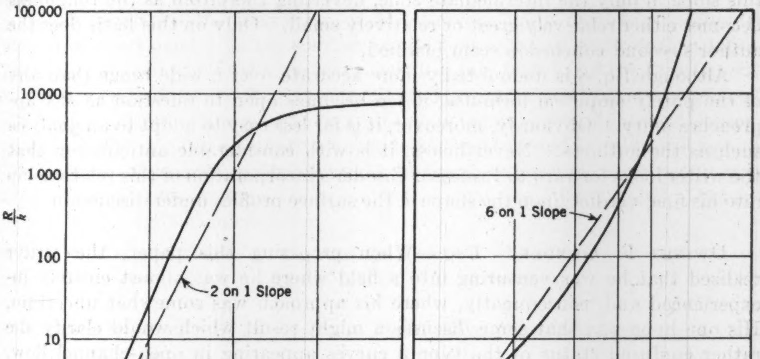

FIG 8

To be explicit, for the case of flow in a very wide channel in which the resistance is independent of viscosity, the Chezy C may be expressed with very close approximation in the Kármán-Prandtl form:

$$\frac{C}{\sqrt{8\,g}} = 2.1 + 2 \log_{10} \frac{R}{k} \qquad (40)$$

in which the factor k is a linear measure of the boundary roughness. (It is to be noted that the dimensionless factor 2.1 is a function of cross-sectional form, and will vary with the proportions of the channel section.) Like R/k, the Bazin parameter $m/R^{1/2}$ and the Manning parameter $R^{1/6}/n$ are measures of relative roughness, the Bazin m in American units obviously having the dimension of $(\text{feet})^{1/2}$, and the Manning n the dimension of $(\text{feet})^{1/6}$; what dimension to ascribe to the Kutter n is a problem, owing to the two different dimensions it appears to have in the Kutter formula. Were Eq. 40 and the Bazin formula both correct, a logarithmic plot of R/k against $R^{1/2}/m$ for identical values of C would appear as a straight line having a slope of 2 on 1; as seen from Fig. 8(*a*), the actual relationship has approximately the required slope only in the range of moderate to excessive roughness. Similarly, were Eq. 40 and the Manning formula in agreement, a similar plot of R/k against $R^{1/6}/n$ would yield a straight line having a 6 on 1 slope, whereas the curve in Fig. 8(*b*) displays this slope in only the intermediate zone, deviating therefrom as the roughness becomes either relatively great or relatively small. Only on this basis does the author's second conclusion seem justified.

Although Eq. 8 is undoubtedly more accurate over a wide range than any of the purely empirical formulas, it too becomes open to question as R/k approaches unity. Obviously, moreover, it is far less easy to adapt to an analysis such as the author's. Nevertheless, it is with considerable anticipation that the writer looks forward to Professor Gunder's incorporation of this relationship into his final verdict upon the shape of the surface profiles under discussion.

Dwight F. Gunder,[19] **Esq.**—When preparing this paper, the writer realized that he was venturing into a field where he was almost entirely inexperienced and, consequently, where his approach was somewhat uncertain. His one hope was that some discussion might result which would clarify the rather confused status of the type 3 curves appearing in open-channel flow. The excellent contributions of the discussers have certainly justified this hope.

Before considering these discussions individually, the author wishes to acknowledge an error in the paper. The point of inflection for the Bazin and Ganguillet-Kutter relations by the straightforward but extremely tedious method of determining the point of inflection was located by finding $\frac{d^2y}{dx^2}$ and solving this equation by approximation. In so doing, a serious error of computation was committed. (Few mathematicians, if such the writer could be called, can do arithmetic.) The much more elegant treatment of this part of the problem by Messrs. Bakhmeteff and Feodoroff clearly showed a discrepancy. In light of this and the experimental findings of the same two discussers, the second of the conclusions of the "Synopsis" should be written as follows:

---

[19] Research Engr. and Associate Prof., Math. and Civ. Eng., Colorado State College, Fort Collins, Colo.

(2) Use of the differential equation of gradually varied flow at depths below both the normal and critical depths should be made with reservations until more experimental work has been done in this region of high velocity flow. The author deeply regrets the inclusion of this error but is glad that it was caught in the discussions.

The suggestions of Messrs. Rohwer and Rouse that certain other specific cases be considered are excellent although they provide rather severe difficulties unless one is to adopt approximate methods which, in turn, are essentially those now used. Further, it seems from the evidence presented by Messrs. Bakhmeteff and Feodoroff that further refinement in the analysis should await additional experimental data relative to the various roughness factors and to the profile curves themselves. As soon as some one obtains some rather complete and reliable data on this particular region of flow, it may be advisable to attack the problem using, say, the Kármán-Prandtl expression for the Cheźy *C*, as is suggested by Professor Rouse. The mechanical difficulties attendant upon attaining a closed solution to this problem are great but not necessarily prohibitive.

With regard to the discussion of Mr. Stevens, only one point probably should be mentioned. In the solution of the flow equation, as Professor Rouse has stated so well, the final form was presented only for what it might be worth to those who had use for it. As a result, this equation was stated in terms of the original variables and parameters with no attempt at simplification, leaving such simplifications or alternative forms to those interested in using the result. The feature which the writer thought obvious, but which apparently Mr. Stevens (and hence perhaps others) missed, is that the differential Eq. 15 can be put in the dimensionless form

$$d\xi = \frac{\eta^{1/3}\,(\eta^3 - \eta^3_c)}{\eta^{10/3} - 1}\,d\eta \ldots\ldots\ldots\ldots\ldots\ldots (41)$$

in which $\eta = \frac{y}{y_o}$, $\eta_c = \frac{y_c}{y_o}$, $\xi = \frac{S_o\,x}{y_o}$. Eq. 17 then reduces to

$$\xi = \eta + 0.306\,\eta^3_c + 0.3\,K_1 \ldots\ldots\ldots\ldots\ldots\ldots (42)$$

in which K_1 is dimensionless and a function of η_c and η only. It is thus seen that the plot of the ξ,η-curves, which give the x,y-curves directly, is a one-parameter family with the parameter η_c. Furthermore, K_1 may be separated into two parts, one of which (say, K_2) is independent of η_c, and the other of which (say, K_3) consists of three or four relatively simple terms involving η and η_c. Thus, the construction of the table which Mr. Stevens recommended as a sentence for the writer could be accomplished in quite a restricted space. It appears as though the "professor" had overestimated the ability of one of his "students." This situation seems inseparable from the learning process.

The writer wishes to acknowledge especially the fine work of Messrs. Bakhmeteff and Feodoroff in correlating the discussion of the various resistance factors and correcting the writer's error, as well as in giving some intimation by experimental studies of the true state of affairs as regards the type 3 curves in open-channel flow.

Finally, the author feels that the excellent discussions have contributed more to the problem than did the original paper, the only merit of which is perhaps that it brought forth these discussions.

THE GREASE PROBLEM IN SEWAGE TREATMENT

By Almon L. Fales [1] and Samuel A. Greeley,[2] Members, Am. Soc. C. E.

With Discussion by Messrs. Arthur D. Weston, Harvey F. Ludwig, W. S. Mahlie, Denis Dickinson, Charles R. Velzy, F. M. Dawson, and Almon L. Fales and Samuel A. Greeley.

Synopsis

Until recent years, municipalities in the United States, situated on the seacoast, have had relatively little difficulty in disposing of their sewage with scant, if any, treatment. In general, the most that was required of such municipalities was the construction of intercepting sewers (to prevent the discharge of sewage from numerous small outlets at the shore) and one or more outfall sewers extending to deep water for disposal by dilution. With increasing population and higher standard of cleanliness, it has become increasingly difficult to dispose of sewage in this manner without creating conditions objectionable to bathing, boating, fishing, and the like.

The offensive conditions have been due primarily to deposits of settling suspended matters and to floating sewage matters, including grease and oil which form "sleek" on the surface. The result in many cases has been that steps have been taken to provide sewage treatment plants for clarification and grease removal. In view of the important relation of grease to the problem of sewage treatment and disposal, the purpose of this paper is to discuss the problems of grease removal in sewage.

Definition of Grease

A standard concept of grease in sewage is that it "includes fats, waxes, free fatty acids, calcium and magnesium soaps, mineral oils, and other non-fat materials" (1).[3] When "grease" is mentioned in connection with sewage and its treatment, almost any combination of these substances may be meant. Sometimes, however, the liquid portions are called "oil" and the solid portions

---

Note.—Published in February, 1942, *Proceedings*.

[1] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

[2] (Greeley & Hansen), Chicago, Ill.

[3] Numerals in parentheses, thus: (1), refer to corresponding items in the Bibliography (Appendix).

"grease." The term "grease" is generally applied to all these materials whether of animal or vegetable origin.

SOURCES OF GREASE IN SEWAGE

In a broad sense, there are three sources of the grease and oil in sewage—domestic, industrial, and automotive. Domestic sources of grease include dwellings, hotels, restaurants, clubs, and institutions, the grease originating in human feces and kitchen slops. Feces contain fatty acids, soap, and neutral fat, whereas kitchen slops contain not only the unused fats from foodstuffs, such as lard, suet, butter and olive oil, but also soaps. The latter include both the sodium soaps and the calcium and magnesium soaps, or mineral soaps, which result from the reactions due to the hardness of the water supply.

Industrial wastes may contain large quantities of grease and oil, particularly those from abattoirs, packing houses, wool-processing plants, rayon plants, tanneries, oil refineries, gas works, canning plants, dairies, bakeries, and laundries.

Automotive sources of oil and grease include garages, repair shops, and automobile-washing plants. Although the larger garages may collect such material and prevent it from entering the sewerage system, many individual owners discharge waste of this kind into the sewers.

CHARACTERISTICS OF GREASE

True fats are compounds of the alcohol glycerol (commonly called glycerin) with the fatty acids, such as oleic, palmitic and stearic, the resulting glycerids being designated as olein, palmitin and stearin (2). Other glycerids are also known. The three mentioned are found in animal fats—the first being a liquid and the others solids.

Fats contain carbon, hydrogen, and oxygen in varying proportions, the chemical structure of the molecules being relatively simple. Fats are among the more stable of organic compounds. The mineral acids attack them, with the result that glycerin and fatty acid are formed. In the presence of alkalis, such as sodium hydroxide, glycerin is liberated and alkali salts of the fatty acids are formed. The latter are known as soaps and, like the fats, are of stable character. Common soaps, soluble in water, are made in the manner indicated, by saponification of fats with sodium hydroxide. Mineral soaps, on the other hand, are insoluble and are precipitated. Soaps in sewage are largely of the latter kind.

The grease in sewage may be either "free" or "combined." The free grease is partly of mineral origin, such as gasoline, kerosene, and fuel oil, and partly of organic origin, such as lard, butter, and cottonseed oil. Most of the combined grease in sewage is soap. Although oil and water are immiscible, one can be dispersed in the other with the aid of a third substance, or emulsifying agent, to form an emulsion. In sewage, oil and water form emulsions, with the aid of soaps and, in this manner, much of the "free" grease is held in a colloidal state.

From a physical standpoint, grease in sewage may be classified as capable of floating, when in emulsion or suspension, or of settling. Soap curds and the lighter oils and greases tend to float. Grease in meat-packing wastes may partly sink and partly flow along in emulsion or in suspension, although some of the material floats. Apparently these types of material tend to rise as the liquid chills. Gas wastes and similar substances may contain relatively heavy tarry residue (which sinks) as well as lighter oils that form a thin film on the surface.

EFFECTS OF GREASE ON RECEIVING WATERWAYS

When sewage is discharged without treatment into rivers or tidal waters, the normal quantity of grease and oil contained in the sewage tends to give a smooth, silky appearance, called "sleek," to the surface of the body of water near the point of discharge. Small quantities of oil can cover large surfaces and, in a general way, the extent of the sleek field in the vicinity of a given outlet depends upon the grease and oil content of the sewage. Such sleek may be detrimental to boating, due to the formation of oily deposits on the sides of pleasure crafts passing through it. Where sleek fields are sufficiently extensive to reach bathing beaches, the use of the beaches may be out of the question, on account of the deposition of oil and grease.

In the case of rivers, an oil film may interfere with natural purification by shutting off the air needed for re-aeration. Spawning places for fish may be damaged by oil, and fish food injured. Oils may impart unpleasant tastes and odors to water supplies. Furthermore, if the water is used for irrigation, oil films may tend to fill up the pores of the soil.

Another ill effect of discharging untreated sewage into bodies of water is the formation of grease balls. According to Edward Wright, M. Am. Soc. C. E. (3),

> "* * * the amount of fats in the sewage from one of the large tannery districts in Massachusetts, which is discharged into the sea, has been so great as to cause the formation of numberless grease balls, varying in size from a large marble to a cantaloupe. They are particularly offensive in connection with the recreational uses of adjacent waters for bathing, * * * Such balls, presumably from the Boston Harbor outfall sewers, were found at an isolated point 66 miles from the harbor."

EFFECTS OF GREASE ON SEWAGE TREATMENT PLANTS

The troubles caused by grease at sewage treatment plants are many and varied, some of them being of rather common occurrence. In fine-screening plants, grease tends to clog the screens and increase the cost of maintenance. In other types of treatment plants, fatty substances may form unsightly scum on the surface of the sewage in channels and tanks, as well as on the side-walls at the surface of the sewage. In sedimentation tanks, grease may interfere with the settling of suspended solids by coating particles of organic matter and causing them to rise to the surface as scum. In some cases, it has been found that grease digested with difficulty and caused trouble in the digestion chambers of Imhoff tanks.

Fats are a deterrent to the biological processes taking place in intermittent sand filters, trickling filters, and activated-sludge plants, in that they coat with a stable film surfaces that otherwise would be subject to microbial action. They may also cause clogging of filters and of trickling-filter nozzles.

Accumulations of grease are likely to cause offensive odors at sewage treatment plants. They may also destroy paint, as shown by experience at the

Marina sewage pumping plant at San Francisco, Calif. According to Joseph Corrao (4),

> "When oil or grease become emulsified with water they very effectively destroy the paints they come in contact with. They dissolve the vehicle, soften the film and make it susceptible to mechanical damage thereby exposing the steel to attack by water, hydrogen sulfide, and other destructive agents."

Oil and grease in sewage may also cause difficulties in sludge disposal. For example, it was reported in 1931 that, at the Calumet works of the Sanitary District of Chicago, Ill., the activated sludge, which was being heat-dried, showed a marked tendency to ignite in the dryer, when oil was prevalent (5). More recently, at the Southwest Works of Chicago, the distillation of grease and other volatile substances in the flash-drying process has caused accumulations on the forced-draft fans and air ducts, which seriously interfere with the operation of the drying system. Furthermore, large amounts of oil and grease tend to make sludge dewatering more difficult. They depreciate the commercial value of sludge as a fertilizer.

Another possible source of difficulty is the entrainment of large quantities of air in sewage before it reaches the sewage treatment plant. In the early months of 1938, at the Wards Island sewage treatment plant in New York, N. Y., thick scum formed on the surface of the preliminary clarifiers, often to a depth of 4 in. (6). The trouble was traced to the fact that air under pressure was entering the sewer system feeding the plant. Scum formation was eliminated by raising the sewage level at the Manhattan and Bronx grit chambers, thus preventing air from being entrained in the raw sewage.

A difficulty of a similar nature occurred at the North Toronto sewage treatment plant in Toronto, Ont., Canada, where the sewage falls 80 ft in a drop shaft before entering the plant. Large quantities of air, entrained in the raw sewage during this drop, caused the grease in the sewage to form thick froth and scum on the surface of the influent channels. The difficulty was overcome by installing water sprays to beat down the scum in these channels or force it into the preliminary sedimentation tanks.

TESTS FOR DETERMINING GREASE IN SEWAGE

The quantity of fats and oils in sewage is commonly determined as ether-soluble matter, by liberating with acid the fatty acids, after evaporating the water, and dissolving them in ether which is then driven off, leaving behind the ether-soluble matter which can be weighed.

Any one of three solvents may be used in the determination of grease, as shown by the following quotation (1):

> "Of the three common fat solvents, petroleum ether, ethyl ether and chloroform, the last extracts the greatest amount of grease, and petroleum ether the smallest. These solvents may extract additional material after the sample has been acidified. This is particularly true of petroleum ether, and to a much smaller extent also true of chloroform. More data are needed regarding the chemical composition of the material extracted by the different solvents, and until this is available it seems best to recommend

> petroleum ether, ethyl ether and chloroform. In reporting results the extracting agent should always be stated. On the insufficient data available, chloroform appears to be the most satisfactory solvent. However, it has not received sufficiently widespread use to warrant discarding the other solvents at this time."

Data on the extraction of lipids from sewage sludge by four different solvents have been furnished by O. J. Knechtges, W. H. Petersen, and F. M. Strong (7). The term "lipids" is intended to designate fatty acids, substances yielding fatty acids on hydrolysis, and other substances that are physically of a fat-like character and can be extracted with fat solvents from biological materials. Four solvents were compared with respect to the quantity of lipid extracted from domestic sludge and packing-house sludge. The results (7) are given in Table 1.

TABLE 1.—PERCENTAGE OF DRY SOLIDS EXTRACTED FROM DRIED SLUDGE BY DIFFERENT FAT SOLVENTS
(Sludge Not Acidified)

Sludge	Petroleum ether	Ethyl ether	Isopropyl ether	Chloroform
Domestic	24.7	23.6	31.1	42.5
Packing-house	18.4	21.3	30.3	38.8

Chloroform extracted the largest percentage of material, and petroleum ether the smallest. In fact, without acidification, chloroform extracted approximately twice as much material as did petroleum ether. Even with acidification of the sludge, petroleum ether removed less material than chloroform did without acidification.

Fractionation of the material extracted from five sludges by petroleum ether and chloroform showed that a fraction totaling from 6% to 19% of the extracts was soluble only in chloroform. This fraction was a black, tar-like material with rather acidic properties. The matter was not investigated further, but it was thought that this material might not be lipoidal in character.

Data on the quantity of grease in sewage, as determined by five different solvents, have been furnished by G. J. Wiest from laboratory studies at Lancaster, Pa. (8). Determinations were made on catch samples of raw sewage from the North sewage treatment plant, the South sewage treatment plant, and the Maple Grove pumping station—the sample from the latter point being representative of strictly domestic sewage. In each case the dried solids were acidified before extraction with the solvent. The results of the Lancaster studies on raw sewage are summarized in Table 2. These results show that, in each sample, chloroform extracted a larger quantity of material than petroleum ether or ethyl ether. Furthermore, chloroform extracted more material than

TABLE 2.—QUANTITIES OF GREASE IN RAW SEWAGE AT LANCASTER, PA., AS DETERMINED WITH FIVE DIFFERENT SOLVENTS

Solvent	North sewage treatment plant	South sewage treatment plant	Maple Grove pumping station
Chloroform	37.0	147.4	39.2
Petroleum ether	7.9	17.2	12.0
Ethyl ether	31.8	70.0	33.4
Carbon tetrachloride	18.7	74.2	42.2
Benzene (benzol)	23.7	62.6	43.0

either carbon tetrachloride or benzene, except in the case of the sample of strictly domestic sewage.

The data presented, although rather meager, are sufficient to indicate that the quantity of grease found in sewage by the recommended methods (1) is dependent mostly upon the solvent used for extraction. According to D. A. Okun, Jun. Am. Soc. C. E., and E. Hurwitz and F. W. Mohlman, the literature indicates that chloroform and ethyl ether extract a larger proportion of non-fatty substances than does petroleum ether, which is more specific for fats and oils (9). Chloroform is said to dissolve resins and waxes in addition to strictly fatty substances. It is evident, therefore, that comparisons of results of grease determinations must be made with caution and with due regard for the solvents used in extraction.

The method of grease determination recommended in "Standard Methods for the Examination of Water and Sewage" (1) has not proved entirely satisfactory, aside from the flexibility that it allows in the solvent to be used for extraction. The evaporation of large quantities of sewage required by this method delays the determination considerably and may cause the loss of some of the grease, which is volatile. Furthermore, according to Mr. Mohlman, evaporation to dryness, after acidification to release fatty substances from soaps, may produce low results because of re-saponification of part of the fats on concentration of the solution (9).

To avoid the necessity for lengthy evaporation, as well as possible re-saponification of fats, Richard Pomeroy and C. M. Wakeman have suggested wet extraction (10). Their method is to agitate the acidified sample with the solvent and separate the two layers in a separatory funnel. Two extractions complete the removal of the soluble material.

TABLE 3.—GREASE IN THE SEWAGE OF VARIOUS CITIES, AS DETERMINED BY EXTRACTION WITH ETHER

City[a]	Sewage flow (gal)[b]	Grease		Year	Observation period (days)
		ppm	Lb per capita daily		
Alliance, Ohio	131	37	0.040	1920	12
Atlanta, Ga. (Intrenchment Creek plant)	167	104	0.145	1920	11
Baltimore, Md.	106	40	0.035	1920	12
Canton, Ohio	64	62	0.033	1920	9

[a] Reference (11) except as noted. [b] Gallons per capita daily. [c] Industrial wastes from tanneries present in large quantities. [d] Data from Toronto.

Mr. Mohlman prefers to pass the sample through a specially prepared filter, dry the material retained, and extract with the solvent in a Soxhlet extraction apparatus (9). The filtrate is shaken with solvent, and the solvent, with whatever grease it may contain, is then added to the extraction flask. In most cases, especially with sludges, the grease in the filtrate may be disregarded.

Quantities of Grease in Sewage

Table 3 contains data on the quantities of grease in the sewage of various cities, as determined by extraction with ether. Similar data for Massachusetts cities are given in Table 4.

TABLE 4.—Grease in the Sewage of Massachusetts Cities, as Determined by Extraction with Ether

Description (1939 data from the Massachusetts Department of Health)	Attleboro	Brockton	Fitchburg	Gardner		Leominster	North Adams	Pittsfield	Worcester
				Gardner area	Templeton area				
Grease, in parts per million..	46	79	45	104	62	43	40	54	80
Period of observation, in days..................	4	5	7	4	7	7	7	7	5

According to these data, the quantity of grease in city sewage ranges from 25 ppm at Reading, Pa., to somewhat more than 100 ppm at Atlanta, Ga., and Gardner, Mass. In cities where the sewage contains large quantities of industrial wastes, the grease content may be very high. Such is the case at Gloversville, N. Y., where, due to large quantities of tannery wastes in the sewage, nearly 500 ppm of grease were found in the sewage in 1921–1922. From Table 3 it will be seen that, on a per-capita basis, the quantity of grease in sewage ranges from 0.02 lb per day at Dayton, Ohio, Houston, Tex., and Reading, to 0.15 lb at Atlanta, and 0.59 lb at Gloversville.

Additional data on the grease content of sewage have been compiled by W. S. Mahlie, but unfortunately the analytical methods used were not recorded (13).

Methods of Removing Grease from Sewage

There are two general methods of separating grease from sewage: First, by the installation of separate tanks or other devices especially designed to retain grease and other floating matters; and second, by the collection of such materials as they float on the surface of sedimentation tanks or settle to the bottom with sludge. Equipment that may be installed for the first method includes skimming tanks, skimming-detritus tanks, and aerated grease-separating tanks. To aid in the subsequent separation of grease by skimming, the sewage may be agitated with air or by mechanical means, or it may be treated with a combination of air and chlorine.

Plain Skimming.—Probably the earliest method of grease removal at sewage treatment plants was that of skimming the grease by hand from the surface of sedimentation tanks or grit chambers, after arresting the floating grease by means of suitable baffles. In a few cases plain skimming tanks have been installed for the purpose of separating scum from the sewage.

A skimming tank is arranged in such a way that floating matter rises in it to the surface of the sewage and remains there until it is skimmed off, while the liquid flows out continuously through deep outlets or under partitions, curtain walls, or deep scum boards. The few American skimming tanks in existence are either elliptical or circular in shape and furnish detention periods of from 1 to 15 min. The submerged outlet is situated opposite the inlet and at a lower elevation, to promote flotation of the scum and removal of any solid matter that may settle. By means of such skimming tanks material such as corks and bits of wood, as well as grease and oil, is removed.

In a few places, tanks have been built for the separation of the heavy, readily settling solids and of the light floating material in single units, called skimming-detritus tanks. In such a tank at Akron, Ohio, floating wooden booms skim the grease from the surface and collect it in front of an adjustable weir, over which it is pushed on to a draining bed. Revolving plows move the grit and other solids settling from the sewage to a central hopper, whence they are pumped with about 20% of the average sewage flow to grit chambers, where the final separation of grit takes place. After passing fine screens, this "underflow" joins the main body of sewage that has passed through the skimming-detritus tanks. There are two tanks in the Akron plant, 55 ft in diameter and 12 ft in maximum depth, which furnish an average detention period of 12.6 min. There are skimming-detritus tanks of a similar type at Allentown, Pa., and Dayton.

At the West Side works of the Sanitary District of Chicago, the sewage, before entering the Imhoff tanks, passes through rectangular tanks with an average detention period of about 15 min. These tanks are equipped with sludge-removal equipment of the scraper-conveyer type, the return flights on the surface serving as skimmers. About 15% of the flow, containing the settled solids and grit, is diverted to the grit chambers.

Although a considerable quantity of objectionable scum may be removed from sewage by skimming tanks and skimming-detritus tanks, it is doubtful whether such tanks alone are capable of removing more than a small proportion of the grease contained in normal sewage.

Sedimentation and Skimming.—A somewhat larger proportion of the grease is often removed from sewage in sedimentation tanks, especially where such tanks are equipped with skimming devices. In this case, part of the grease rises to the surface and is skimmed off, while another portion settles to the bottom and forms part of the sludge.

In installations equipped with mechanical apparatus for sludge removal, this apparatus, or an attachment to it, may also be used to remove scum. The scraper-conveyer type of mechanism has already been mentioned. Another device adapted to the removal of floating matter is a commercially patented mechanism that consists of a bridge traveling on rails along the longitudinal walls of the tank, with a scraper attached to the bridge by hinged arms. The scraper is used to force the sludge into hoppers at the influent end of the tank and, when raised to the surface of the sewage, it is used to skim the tank.

In tanks where the sludge-removal mechanism cannot be readily adapted for use in skimming, a system of water piping with small nozzles, as used by H. B.

Allen in the Imhoff tanks at Fitchburg, Mass., may be of value. The nozzles—horizontal hack-saw cuts in vertical pipes—discharge jets of water almost horizontally over the surface, driving the accumulated grease and oil to points where they can be collected. An installation of this type in the preliminary sedimentation tanks of the North Toronto plant has given good results.

In some plants grease is removed from the surface of sedimentation tanks by hand. It may be skimmed off by means of dippers, drawn off by lowering inverted sluice gates, or pushed into troughs or bays by squeegees.

Since the determination of fats is not ordinarily made in settled sewage, the available data on the removal of grease from sewage by sedimentation tanks are not plentiful. At the Westerly plant in Cleveland, Ohio, according to the late George B. Gascoigne, M. Am. Soc. C. E., a study of ether-soluble matter was made on 28 weekly composites from January to June in 1934, when the grease catchers were not in operation (12). This study showed the average grease content of the raw sewage to be 66 ppm and that of the settled sewage 46 ppm, with a removal of 20 ppm, or 30%. In experiments on sewage of the Boston Main Drainage system in 1935, the results indicated that about 40% of the 46 ppm of grease present in the raw sewage, as determined by ether extraction, could be removed by skimming and sedimentation in a 2-hr detention period, leaving 28 ppm in the effluent (14). Similar results were obtained by the same investigators in experiments on sewage of the North Metropolitan sewerage system in 1935 and 1936.

At the Sewage Treatment Works of Buffalo, N. Y., determinations have been made of the grease in weekly composites of acidified daily samples of sewage leaving the grit chambers and of the effluent from the sedimentation tanks, by petroleum-ether extraction of solids removed by filtering through absorbent cotton. The conduits, through which the sewage passes to the sedimentation tanks, are aerated to prevent deposition of solids and keep the sewage fresh. The sedimentation tanks have a displacement period of 80 min at rated capacity. They are provided with mechanical equipment for removing the sludge and scum.

TABLE 5.—GREASE REMOVAL BY SEDIMENTATION TANKS AT BUFFALO, N. Y., SEWAGE TREATMENT WORKS DURING 1940

Month	GREASE BY PETROLEUM-ETHER EXTRACTION OF FILTERED SOLIDS				Average daily flow of sewage (mgd)
	Grit chamber effluent (ppm)	Sedimentation tank effluent (ppm)	Removed by sedimentation tanks (ppm)	Removal (%)	
Jan.	50.2	42.7	7.8	15.5	127
Feb.	54.7	46.2	8.5	15.6	141
March	53.8	48.8	5.0	9.3	183
April	45.8	43.3	2.5	5.4	174
May	34.4	27.2	7.2	21.2	129
June	37.1	31.5	5.6	15.1	127
July	39.9	23.1	16.8	42.0	118
Aug.	23.4	15.6	7.8	33.3	128
Sept.	38.2	29.7	8.5	22.2	125
Oct.	40.5	24.1	16.4	40.5	113
Nov.	29.8	29.0	0.8	2.8	161
Dec.	23.1	16.9	6.2	26.8	202
Aver.	39.2	31.5	7.7	19.6	144

A monthly summary of data on grease removal by the sedimentation tanks at Buffalo during 1940 is given in Table 5. (Grease content was determined in weekly composites of daily samples acidified with sulfuric acid. The averages were not weighted. The data were furnished by C. R. Velzy, M. Am. Soc. C.

E.) The monthly average grease content of the sewage, as determined in the grit-chamber effluent, varied from 54.7 to 23.1 ppm, averaging 39.2 ppm, for the year, and the proportion of grease removed by the sedimentation tanks varied from 42.0 to 2.8%, averaging 19.6% for the year. There does not seem to have been any definite relation between the quantity of grease in the sewage and the percentage removed.

Data on the removal of grease by settling tanks at sewage treatment plants of Massachusetts cities (15) are presented in Table 6. The data for fats, or grease, are averages for 1939 as determined by ether extraction of the solids of composite samples of raw and settled sewage, collected in most cases at approximately bi-monthly intervals. Table 6 shows that of 43 to 80 ppm of grease in the raw sewage at these plants, from 8% to 72% was removed by the settling tanks. There appears to be no definite relation between detention period and removal of grease at the different plants.

TABLE 6.—AVERAGE GREASE REMOVAL BY SETTLING TANKS AT SEWAGE TREATMENT PLANTS OF MASSACHUSETTS CITIES DURING 1939

City	Detention period (hr)	FATS BY ETHER EXTRACTION (PPM)			Fats removed (%)
		Raw sewage	Settled sewage	Removed

AERATION PRIOR TO SKIMMING

The separation of grease and oil from sewage by flotation is facilitated by a short period of pre-aeration, although, as stated in the report of the Boston experiments of 1935–1936 (14), there is some doubt whether pre-aeration materially increases the over-all removal of grease from sewage by settling tanks. The assistance of aeration in flotation may be due in part to the de-emulsifying of the oil, which is thus separated from the sewage, and in part to physical action, as the grease adheres to the small air bubbles and is carried to the surface with them.

Several systems have been developed for the removal of grease and oil by aeration. Karl Imhoff, M. Am. Soc. C. E., has built combined aerating and skimming tanks at several plants in the Ruhr District in Germany, using detention periods of from 3 to 5 min. Tanks of this type have been installed at Pasadena, Calif., and Springfield, Ill. The tank in the latter city, which was placed in operation in 1931, is 16 ft by 35 ft in plan, with a double row of air-diffuser plates through the center at the bottom and two longitudinal baffles, which form a stilling chamber along each side for the accumulation of grease. The detention period is 8 min at the average flow of 7.5 mgd (16).

At Whittier, Calif., there is an aeration chamber, 40 ft long, 10 ft wide, and 9 ft deep, set in front of a skimming chamber, 10 ft square, in which the scum is collected in a trough while the effluent is drawn off at the bottom. The aeration system is of the ridge-and-furrow type. At Hamilton, N. Y., there is an aerated grease-separating tank, in which the grease settles in pockets at one end and is removed by means of 2-in. suction pipes (17).

Recently tanks or channels have been installed at some sewage treatment plants, to provide a short period of aeration preceding treatment in sedimentation tanks equipped with skimming devices. After passing through the pre-aeration tanks, the grease, oil, and other floating matter are collected and removed by the skimming devices within the sedimentation tanks. For example, at the District of Columbia plant the sewage passes through three aerated grease separating tanks, each 15 ft wide, 78 ft long, and 15.5 ft in maximum water depth. Each tank is equipped with two rows of diffuser plates along one side. With all three tanks in operation, the detention period in the grease-separating units is designed to be 4 min at an average flow of 130 mgd. After the grease-separating treatment, the sewage flows into twelve sedimentation tanks with an average detention period of 2 hr, equipped with clarifier mechanisms for sludge removal and skimming baffles for removing scum.

At San Antonio, Tex., and Lancaster, Pa., air-diffuser plates have been installed in the distribution channels leading to the preliminary sedimentation tanks. The sewage is subjected to a short period of aeration and the oil, grease, and other floating matters are skimmed mechanically from the surface of the tanks.

In experiments at Los Angeles, Calif., aeration was found to aid flotation of grease and oil and form a thick, tenacious scum that was easily removed from the grease skimmer (18). Aeration was accomplished by discharging small streams of screened sewage into the inlet channel at high velocity, the nozzles being placed 2 in. above the surface of the sewage. Removals of 50% to 75% of the free grease were obtained with detention periods of from 2 to 3 min.

At Rochelle, Ill., there is a combined grease-separating and flocculation tank, equipped with an "American" downdraft mechanism, in which the sewage is treated with diffused air in the presence of gentle agitation. After passing through this tank, which provides a detention period of 20 to 30 min, the sewage enters two preliminary sedimentation tanks, equipped with skimming mechanisms. A large proportion of the separated grease is skimmed directly from the surface of the separating tank. Removals of grease, determined by ether extraction, ranging from 48% to 69%, have been reported for the grease-separating and primary sedimentation tank units at this plant.

At the Richmond-Sunset sewage treatment plant in San Francisco, the sewage passes through two "grit-grease" tanks—aerated Imhoff-type tanks—which provide a detention period of 10 min (19). The grease is carried by water sprays to a movable trough and thence to a sump. Following the "grit-grease" tanks are two mechanical flocculation tanks with a detention period of 30 min, the effluent from which flows into two sedimentation tanks with a detention period of 1.5 hr at the average flow. Some of the grease is liberated in the inlet channel to the sedimentation tanks. Scum forming on the sedimentation tanks themselves is removed by water sprays. During an investigation in January, February, and March, 1940, comprising 29 tests on day sewage, the removal of grease, as determined by chloroform extraction, ranged from about 57% for raw sewages containing 115 ppm of grease to about 46% for those containing 60 ppm of grease.

According to Mr. Gascoigne, there were two grease catchers in operation at the Westerly plant in Cleveland during 1933, treating 5 to 20 mgd (12). One of these tanks was of the Imhoff type and the other was similar in design, except for the inside baffling arrangement. Air was supplied to the influent channels and tanks at a rate of 0.023 cu ft per gal. A study of the ether-soluble matter at this plant for two months in 1933 showed the following results (in parts per million):

FIG. 1.—AT THE RICHMOND-SUNSET SEWAGE TREATMENT PLANT IN SAN FRANCISCO, THE SEWAGE PASSES THROUGH TWO GRIT-GREASE TANKS

Total ether-soluble matter in raw sewage	70
Total ether-soluble matter in settled sewage	46
Removal (34%)	24

This grease was removed in the following forms:

Skimmings from Imhoff tanks	10.5
Skimmings from grease catchers	2.5
Attached to sludge particles	11.0
Total	24.0

Data on the removal of grease at the sewage treatment plant in Dodge City, Kans., during four months of 1932 have been furnished by F. C. Roe (20). At this plant the aeration period was designed to be approximately 13 min. Based on four monthly composite samples, the removal of grease ranged from 44% to 63%, while the quantity of grease in the raw sewage ranged from 25 to 216 ppm.

AERO-CHLORINATION

To improve the recovery of grease from wool-washing wastes, Jean deRaeve used chlorine (21). He found that the fats were in an emulsified state, protected by a gelatinous nitrogenous colloid, and that chlorine destroyed this protective colloid, allowing the liberated grease to be recovered by flotation and skimming.

An experiment on the use of chlorine as an aid in the removal of grease from sewage was undertaken by H. A. Faber at the sewage treatment plant in Woonsocket, R. I. (22). Here the sewage has a high grease content because it receives wastes from such industries as wool scouring, rayon manufacture, and weaving processes. Gaseous chlorine was injected directly into the compressed air line serving the grease-removal tank. The experiment consisted of aeration with chlorinated air for one week and aeration in the usual manner for the following week. At the end of each 24-hr period the total grease collected in the form of scum on the tank was removed and weighed. The results indicated that a gaseous chlorine dose averaging less than 1.5 ppm effected increased grease removal by skimming, the quantity removed with chlorine and air ranging from 189% to 442% of that removed with air alone.

A group of similar experiments conducted by C. E. Keefer, M. Am. Soc. C. E., and E. C. Cromwell at Baltimore, Md., likewise showed increased grease removals by skimming where chlorine was used. With chlorine injected into the air pipe serving the grease-removal tank, removals ranged from 149% to 847% of the removals when air alone was used (23).

At the South plant in Lancaster, Mr. Wiest tried a form of aero-chlorination under plant-scale conditions in 1938 (24). A chlorinator was set up to feed chlorine in solution directly to the raw sewage just ahead of air diffusion in the pre-aeration channel. The sewage flow was maintained at 4.0 mgd and chlorine was applied at 2.0 ppm. Three tests were run for at least five days each—in the first, neither air nor chlorine was used; in the second, aeration alone was used; and in the third, aero-chlorination was utilized. The results were gaged by determining the grease content of the raw sewage and the effluent from the primary sedimentation tanks, using petroleum ether as a solvent. The removal of grease by sedimentation and skimming during the three tests was as follows:

Description	Percentage removal of grease
Without aeration or chlorination	38
With aeration alone	50
With aero-chlorination	80

During 1939 the aero-chlorination process was placed in operation at the Westerly plant in Cleveland, Ohio, as well as at the sewage treatment plant in Bellefontaine, Ohio. At Dallas, Tex., a treatment plant containing a grease-removal unit was placed in operation in 1940 (25). The grease-removal unit provides a total detention period of 8 min for design flows. During the first 4 min air alone is applied, and the second 4 min consist of aero-chlorination. The ridge-and-furrow type of aeration was selected. The separated grease is swept by flat water sprays to an area of the grease-removal unit, from which it is automatically removed to a scum box at time-clock intervals.

At present (1941) insufficient operating data are available to form a basis for a sound conclusion in regard to the value of aero-chlorination in the over-all removal of grease from sewage.

Other Methods of Grease Removal

For many years sewage treatment plants for residential and institutional sewage have been protected by grease traps, for collecting grease and soap from kitchen and laundry wastes before they are discharged to the sewer. The method is to pass the wastes through a reservoir of sufficient capacity to reduce the temperature of the hot wastes, thus permitting the grease to separate and rise to the surface, whence it may be removed by skimming. During the previous World War, many grease traps were constructed at army camps, where the practice was to clean each trap once a week or every other week. At many of the present National Defense projects, a grease interceptor is being installed for each kitchen sink within the building. The size of the grease interceptor is based on the rate of flow to be passed through it.

The removal of grease from sewage by acid treatment has been practiced at Bradford, England, for many years. Here the sewage contains large amounts of grease due to wool scouring wastes discharged into the sewers. The grease is recovered and put upon the market.

The Miles process of sewage treatment consists of the addition of acid to precipitate solids in the form of sludge which can be dried and degreased, thereby producing for sale both fertilizer and grease. The process has not been adopted in the United States for treatment of domestic sewage, although acid precipitation is used for the treatment of certain kinds of industrial wastes. Very high removal of fats by acid precipitation was reported by R. S. Weston, M. Am. Soc. C. E., and E. S. Dorr in experiments at Boston, Mass., the ether-soluble matter in the sewage being 303 lb per million gallons and in the sludge 430 lb per million gallons (26). This increase was attributed to the decomposition of soaps by the acid. In experiments at New Haven, Conn., C. E. A. Winslow and F. W. Mohlman recorded a removal of approximately 100% of the grease by acid treatment (27).

Disposal of Grease

Grease is removed from sewage in two forms—namely, sludge and scum. Except in the case of acid treatment, the grease which settles with the sludge is disposed of with the latter. Grease removed from sewage by acid treatment may be recovered. At Bradford, England, part of the grease is converted into such products as soap powders, metallic soaps, lubricants, and pitch (28). Results obtained with a pilot plant led to the design of a full-scale plant, which was under construction in 1938, to handle about one third of the output of raw grease.

Grease and oil removed from sewage in the form of scum may be disposed of by burial, incineration, or digestion with other sewage solids. In some places the oil skimmed from sewage has been used on roads.

The materials collected on the surface of the skimming-detritus tanks at Akron are drawn to small draining beds, and the drained material is disposed of by burial with the dewatered Imhoff sludge. At the plant of the Rahway Valley Joint Meeting in New Jersey, the grease removed from the settling tanks is flushed to a grease-separation chamber, in which the grease is separated from its carrying water by flotation (29). It is then scraped into buckets and buried, although it may be burned in the screenings incinerator. The scum from the skimming-detritus tanks at Allentown and Dayton is incinerated with screenings.

Although troubles of various kinds have been reported, due to the disposal of grease and oil by digestion with sludge (2) (5) (13), the fact remains that it is now common practice to discharge grease, removed from sewage in the form of scum, into separate sludge-digestion tanks for disposal. Among the sewage treatment plants where this method of disposal is used are those for the District of Columbia, and New Rochelle, N. Y.; and the Terminal Island plant at Los Angeles and the Richmond-Sunset plant at San Francisco.

At the District of Columbia plant, where grease is digested with sludge in heated digestion tanks, equipped with fixed covers, no trouble has been experienced in operation. At Rochelle, Ill., where grease is introduced into a heated sludge-digestion tank, equipped with a floating cover, some trouble has been caused by formation of a thick layer of scum in the tank, at one time reaching a thickness of 9 ft. The operator has found that trouble can be avoided by drawing supernatant liquor from a very high elevation at frequent intervals.

At the Terminal Island plant, grease was formerly discharged upon sand beds, dried and burned with the aid of surplus gas from the digester (30). Since this method of disposal proved cumbersome and laborious, it has been superseded by that of discharge into the digester. At the Richmond-Sunset plant, grease is discharged into the sludge-thickening tanks, whence the combined ground screenings, grease, and sludge are pumped into the primary unit of a two-stage sludge-digestion system, equipped with turbo-mixers, heating coils, and a stationary steel dome (19).

CONCLUSION

The grease content of the sewage is an important consideration in the problem of sewage treatment and disposal.

The quantity of "grease" found in sewage by the present standard method of analysis is largely dependent upon which of the three standard solvents is used for extraction. Differences in the solvent used may lead to confusion when an attempt is made to compare the grease content of sewages of different cities and, in some cases, that of the sewage of a given city for different years. Furthermore, the standard method of determination of grease in sewage has not proved entirely satisfactory, aside from the choice of solvent which is allowed. Consequently, the following steps appear to be desirable:

(1) Agreement upon an answer to the question as to what substances should be included in the term "grease";

(2) Adoption of a standard method which is most suitable for determination of grease in sewage as thus defined; and

(3) Accumulation of data on grease in sewage, effluents, and sludge based upon this standard method.

The data presented indicate that a considerable proportion of the ether-soluble matter in sewage can be removed by sedimentation and plain skimming. Moreover, the available data show, in general, that a somewhat larger proportion can be removed if the sewage is aerated prior to sedimentation and skimming. Experiments indicate, furthermore, that aero-chlorination prior to sedimentation and skimming accomplishes a still larger removal of grease. At the present time, however, insufficient operating data are available to form a basis for a sound conclusion relative to the value of pre-aeration and of aero-chlorination in the over-all removal of grease from sewage.

DISCUSSION

Arthur D. Weston,[4] M. Am. Soc. C. E.—The need for adequate means of grease removal in the partial treatment of sewage is well illustrated by the discharge into Boston Harbor and its tidal estuaries of some 244 mgd of sewage from a contributing population of about 1,840,000 persons in the Boston metropolitan area from three different outlets. The sewage from these outlets is chiefly of domestic origin and during the period 1935–1936 had a total suspended solids content from about 119 to 256 ppm, or 0.13 to 0.28 lb per capita per 24 hr; a 5-day B.O.D. from about 119 to 249 ppm, or 0.13 to 0.28 lb per capita per 24 hr; and ether-soluble fats from about 34 to 83 ppm, or 0.04 to 0.09 lb per capita per 24 hr. The diluting body of water into which this sewage is discharged is typical of the salt water of the harbors along the New England coast, is reasonably free from pollution except that from the sewers of the Metropolitan Sewerage districts and the Boston Main Drainage District, and has a chloride content of about 17,000 ppm. Oxygen tests of the harbor waters have shown ample oxygen. The sewage from the Boston Main Drainage District is discharged at the surface on the second and third hours of the outgoing tide from storage tanks, whereas the sewage from the North and South Metropolitan Sewerage districts is discharged continuously through outlets located from 30 to 50 ft below mean low tide. Definite nuisances have prevailed from bacterial pollution of the waters by the sewage and from slick or sleek fields.

Studies made under the direction of the writer (31) in 1935 and 1936 showed sleek areas as large as 2,940 acres in connection with the Boston Main Drainage System, 2,050 acres in connection with the North Metropolitan Sewerage System, and 6,820 acres in connection with the South Metropolitan Sewerage System. These areas are not only esthetically objectionable because of the use of the harbor waters for yachting and recreation, but the floating solids, consisting of wood, oil, grease, soap, and other debris, especially the grease and oil (which are characteristic of sewage and commonly found along the edges of the sleek areas), have been known to reach shore areas highly developed as summer resorts and bathing beaches, and areas normally well suited for the growing of shellfish. The authors cite Mr. Wright (3) as reporting grease balls, presumably from the outfall sewers of Boston, found at an isolated point 66 miles from Boston Harbor (see heading "Effects of Grease on Receiving Waterways").

With a view to remedying these conditions, numerous studies have been conducted to ascertain the most practicable means of treating and disposing of the sewage from the three sewerage systems. These studies included certain experiments to determine methods of removing grease, oil, and other matters from the sewage but with no thought in mind of salvaging the fats. Salvaging matters from sewage was investigated by the Boston Main Drainage District under Edgar S. Dorr and Robert Spurr Weston in 1911 (as mentioned by the authors under "Other Methods of Grease Removal"), and by the Massachusetts

Clark, at that time director of the Water and Sewage Laboratories and the Lawrence Experiment Station of the Massachusetts Department of Public Health, concluded that the recovery of grease from sewage was not economical and that the removal of organic matter by plain sedimentation was nearly as good as by the aforementioned patented process, and considerably cheaper.

[a] For exceptions to the number of samples,

The studies (31) made in 1935 and 1936 on the removal of fats from the sewage included small-scale experiments with the use of tanks on the sewage of the

North and South Metropolitan Sewerage districts and the sewage of the Boston Main Drainage District, and large-scale experiments on the sewage of the Boston Main Drainage District. The latter experiments made use of one of the tanks of this district that is normally used to store the sewage for discharge on the second and third hours of the outgoing tide.

The small-scale experimental plant consisted of small tanks 2 ft by 5 ft in plan and 2 ft deep, equipped for fine screening, grease removal, and plain sedimentation. (The tank for screening had a channel 6 in. wide at the influent and effluent ends, which flared to a width of 18 in. at the center where screens of slotted yellow brass 18 in. by 21 in. could be placed.) The screens used in the experiments were of three sizes of slots: $\frac{1}{16}$ in., $\frac{3}{32}$ in., and $\frac{1}{8}$ in. by 2 in. long.

The small tank used for plain fill-and-draw sedimentation tests and for grease removal with aeration was 4 ft by 5 ft in plan and 5 ft deep. This tank was fitted on all sides except the influent side with sloping false bottoms 30 in. on 20 in. It had parallel wooden baffles spaced 1 ft 4 in. apart, dividing the tank into three channels and extending within a foot of the effluent end where a wooden cross baffle spread across the tank. All baffles extended to within about 6 in. of the bottom. The parallel longitudinal baffles had $\frac{1}{8}$-in. metal baffles that could be adjusted to the level of sewage in the tank. The cross baffle at the effluent end extended above the sewage flow. When aeration was required, two removable porous diffuser plates were placed inside the center at the bottom of the center channel, and the sewage entering the tank at the end of

in the case of B.O.D. and fats, see text.

the center compartment was forced over the longitudinal baffles and under and into the center channel again by a spiral motion. The grease collected on the surface was retained by the cross baffle. Air in the amount of about 0.1 cu ft per gal of sewage was applied.

The larger tank used for plain sedimentation, both for intermittent and continuous-flow experiments, was 4 ft by 7 ft in plan and 6 ft deep. Sewage entered this tank through two elbows that diverted the sewage back against the inlet end of the tank. About 1 ft from the influent end a cross baffle extended to within 1 ft of the tank bottom. A semicircular trough 6 in. in diameter, located about 1 ft from the effluent end of the tank and protected by a skimming baffle, was used to collect the settled sewage. Weir boxes 6 in. by 6 ft in plan and 6 in. deep were fitted with three baffles to smooth the flow at the entrance of the tank, and a triangular brass weir was used to measure the flow. The sewage flow during continuous-flow tests varied from 9 to 35 gal per min.

In the continuous-flow sedimentation tests, samples of the influent were collected as near as practicable to the influent pipe, and samples of the effluent were collected at the weir box. These samples were composite, consisting of ½-pt portions collected every 0.5 hr over a period of 8 hr. The dissolved-oxygen tests during the continuous-flow experiments were on samples collected every 2 hr. The samples collected during the intermittent sedimentation tests consisted of composite samples of the influent collected during the period of filling of the tank and a 2-qt sample of the settled sewage collected at the end of the detention period. The dissolved-oxygen samples during the intermittent sedimentation tests were taken at the completion of the tank filling and at the end of the detention period. During the pre-aeration sedimentation tests, composite samples of ½-pt portions were collected every 0.5 hr over a period of 8 hr from the influent to the degreasing tank, the influent to the settling tank, and the final effluent. Dissolved-oxygen samples were taken at these locations every 2 hr. Table 7 shows the results of average analyses of the samples of raw sewage collected during the tests from the three sewerage systems in question.

Table 8 shows the results of the analyses made during the plain sedimentation tests. This table includes only those samples having an initial suspended solids content of 100 to 300 ppm. The number of samples listed varied, in the case of B.O.D. and fats, as follows (compare Table 8):

Detention time	B.O.D.	Fats
1 hr	17	18
1 hr	..	8
2 hr	7	..
3 hr	17	17
4 hr	10	..

The results of these small experimental plant tests showed that, although the fine screens removed the larger suspended and floating solids, they removed only a small amount of grease or fats, one of the principal causes of complaint of the discharge of sewage into Boston Harbor. Only 5% to 8% of the suspended solids were removed by fine screens as compared with about 50% by sedimentation. The authors mention these tests (see "Methods of Removing

Grease from Sewage: Sedimentation and Skimming") and refer to the raw sewage of the Boston Main Drainage System where about 40% of the 46 ppm of grease could be removed by skimming and sedimentation (14). Pre-aeration of the sewage was not successful in the over-all removal of fats and would indicate that the use of air alone, before sedimentation, in connection with these sewages would not be justified.

One of the existing storage tanks was used for the large-scale experiments on the sewage of the Boston Main Drainage District. This tank, which is trapezoidal in shape with sloping ends, is 162 ft wide and has an average length of 612 ft. In order that it might serve as well as practicable as a sedimentation basin, it was equipped with a dike and skimming baffle, and gates were installed to prevent sewage from flowing out at the bottom of the tank. Five of the outlets at the end of the tank were closed by bulkheads, and the two end openings were closed by sliding wooden sluice-gates. The dike was a triangular-shaped wooden structure about 9 ft high and 16 ft on the two equal sides, and extended symmetrically from the end wall of the basin to enclose one of the existing arched openings. The opening was the only outlet of the tank after bulkheading and gating the other openings, and it acted as an outlet for the tank during the experiments. The top of the dike formed the crest of two sharp-edged weirs each 13 ft long. The skimming baffle was a floating vertical wooden structure 3 ft deep, of which 2 ft were submerged, held 6 ft out from, and parallel to, the sides of the dike by spreaders. The spreaders were so connected as to permit the baffle to rise and fall with the level of the sewage in the tank.

In the first experiments the settled sewage was stored in the other three remaining tanks used for the storage of the sewage for discharge on the second and third hours of the outgoing tide. In later experiments the settled sewage was permitted to discharge into the harbor continuously. Analyses were made of the raw and settled sewage during the experiments and, in the case of the continuous discharge, aerial photographs were taken to show the difference in extent and character of the sleek areas in the harbor resulting from the intermittent discharge of stored raw sewage, and the continuous discharge of settled sewage. Measurements made of the flow of sewage through the experimental tank showed that the average flow was about 60 mgd and that the detention period varied from 1.7 to 5.8 hr, with an average of 2.8 hr. Table 9 shows the results of these settling tests.

Suspended solids....	119	51.5	56.7

It will be seen from Tables 7 to 9 that the raw sewage during these large-scale experiments was somewhat weaker than the sewage of the small-scale experiments. The samples collected from hour to hour showed that the sewage was strongest during the afternoon and early evening and weakest during the early morning hours. The purification obtained in the larger tank compared favorably with that of the smaller units.

It was found that the amount of scum, garbage, and other floating matter retained by the skimmers was much greater than expected, and rough estimates indicate that as much as 40 cu ft of such material per million gallons of sewage were held back.

Although he was not entirely satisfied with the results of the large-scale experiments (because the tank used was not well suited for sedimentation), the writer was convinced that a comparison of the results of the various experiments with the aerial photographs of sleek areas shows that proper settling and skimming of the sewage will result in improved conditions in the harbor by greatly diminishing the sleek areas.

Tests made during 1940 relative to clarification of the sewage at Nut Island included the use of certain coagulants. The raw sewage in this case had the following average composition:

Description	ppm
Albuminoid ammonia	3.73
Oxygen consumed	33
Turbidity	130
Suspended solids	115
Fats	27

The result of these experiments is given in Table 10. Tests made by stirring some of this sewage for 15 min, followed by 1 hr of settling, showed a 27% decrease in turbidity over settling alone. Later tests were made to determine the effect of stirring the sewage prior to settling. In this case, since the sewage was received at different times, there was a decided difference in its strength, and each run was treated separately. Turbidity, suspended solids, and fats were determined for the raw sewage; for sewage that had settled 1 hr; for raw sewage that had been stirred 15 min and settled 1 hr; and for sewage that had been stirred 15 min with 8% by volume of sludge settled out of the five bottles, and settled 1 hr. Stirring the raw sewage gave an appreciable reduction in suspended solids over that due to settling alone. Stirring with additional sludge showed little effect. The use of the modified, rapid type of filter gave the best results (see Table 11, items 1 to 18). In the tests shown in Table 11, items 19 to 36, samples stirred with 10% (by volume) of returned sludge gave poorer results than stirring the raw sewage alone.

[a] Grains per gallon, plus sedimentation.

Tests were made on samples collected on February 27 and 28, 1940, of the raw sewage and of the sewage after 1 hr of settling. The sludge collected from five 1-gal bottles was settled and elutriated several times with tap water. About 10% by volume of this sludge was added to portions of the different sewages, aerated 10 min, and then stirred 5 min and settled 1 hr.

Another sludge was prepared by coagulating a gallon of sewage from Lawrence, Mass., with alum and collecting the precipitate. This precipitate was then mixed with another gallon of Lawrence sewage and the resulting sludge collected and concentrated; 10% of this sludge by volume was stirred 15 min with the different Boston sewages and then settled 1 hr. This last sludge was intended to show the effect of a return sludge from the precipitation of Boston sewage with alum. Lawrence sewage, however, was used in preparing this sludge because there was not enough sludge from the Boston sewage.

On the whole, stirring Boston sewage with added sludge has shown very little beneficial action over stirring the raw sewage alone, but with some lots of sewage the sludge did show improved results. It was conceded, however, that the action was so uncertain as to make its value doubtful, and there was a tendency for such sludge, after it had gathered up colloidal or fine suspended matter, to give it back later into the sewage being treated. This condition is similar to the condition found at the Lawrence Experiment Station from stirring ferric and manganese hydroxides in water. Table 11, items 37 to 54, shows the results of these experiments.

It was the opinion of George O. Adams, chief chemist at the Lawrence Experiment Station, that more satisfactory results could probably be obtained from these experiments if the period of stirring were longer, preferably twice as long. It also is his opinion that the reason for greater removal by plain sedimentation of the sewage from the South Metropolitan Sewerage System than is found in some other places is due to the presence of salt water in this sewage, resulting in the precipitation of the soluble soap as insoluble calcium soaps, thereby increasing the fats removed by plain sedimentation. He was of the opinion that 20% more fat could be removed by aeration than by stirring, these fats to be removed chiefly in surface scum which could be skimmed off. It was interesting to note that in the plain sedimentation tests there was an average removal of 71% of the suspended solids in 15 min, whereas 15 min of stirring increased the removal to 81%. It was also his opinion that aero-chlorination would be desirable, provided that the results warranted the cost; but it was his opinion that aero-chlorination would have little effect on the subsequent removal of the suspended solids.

Experiments were made in 1934 by the Massachusetts Department of Public Health in connection with the disposal of sewage from the South Essex Sewerage District for the removal of fats. The sewage of this district is from Salem and Peabody, Mass., where there are many tanneries and other industries having. wastes containing considerable quantities of fats; from the City of Beverly, Mass., where the sewage is chiefly domestic in character; and from a large mental health hospital and certain other institutions. The average flow of sewage from this district at the time the tests were made was about 13 mgd (with average flows during weeks of minimum flow of 7.27 mgd and average flows during weeks of maximum flow of 25.80 mgd). It is estimated that the total population served at that time was 94,850. The sewage disposal works of

[d] Raw sewage passed through modified, rapid type of filter.

the district are such that the sewage from Beverly and the institutions is pumped into the same outfall sewer that receives the sewage from Salem and Peabody. The point of outfall is in the outer limits of the Salem-Beverly harbors, about 8,300 ft from shore, where the water at low tide is about 30 ft deep.

The Salem and Peabody sewage combined had a suspended solids content equivalent to about 1.33 lb per capita per day and a fat content of about 1.15 lb per capita per day. The combined sewage from the City of Beverly and the institutions had a suspended solids content of 0.14 lb, and a fat content of 0.05 lb, per capita per day.

The experiments for the removal of fats from the sewage were in connection only with the sewage from Salem and Peabody and consisted of tests to determine the amount of fats removed by fill-and-draw sedimentation, by aeration followed by sedimentation, and by continuous flow with the use of a skimming baffle. Two circular wooden tanks of 2,000-gal and 400-gal capacity were used, into which the sewage was pumped from the trunk sewer of the system at a point about 1 ft below the normal flow line in the sewer. The connecting piping was so arranged that the tanks could be operated in series or in parallel. When air was applied, the average rate of diffusion was 0.18 cu ft per gal of sewage through a filtros plate set in the bottom of the tank.

The fill-and-draw, plain, sedimentation tests without the use of air showed that, with a detention period of 7 to 10 min, the removal of fats was 57.9%, or about 400 lb per million gallons of sewage treated. The amount of fats removed by skimming after 7 min of sedimentation was equal to 0.6% of the total fats in the sewage treated. Tests made with the application of air for a period of 7 min, followed by quiescent sedimentation for an additional 7 min, showed a removal of fats of 57.3%, or 425 lb per million gallons, and the fats removed by skimming were equal to about 2.0% of the total fats in the raw sewage. It should be stated that the tests with and without the use of air are not wholly comparable as the sewage to which the air was applied had a higher fat content than the sewage which received no air application.

In the continuous-flow experiments, a detention period of 37 min was provided by throttling the pump delivering sewage to the tank. Here the fat content of the sewage was 108 ppm as compared with 83 ppm in the fill-and-draw tests and 89 ppm in the test with air. This continuous-flow test showed a removal of fats of 54%, which is equivalent to 484 lb of fats per million gallons of sewage.

In these experiments an average of ten samples of the sludge that settled out in the tanks during various forms of sedimentation contained 16.2% of fats. Tests also were made in connection with the sewage of Salem and Beverly to determine the separation of fats from the sewage by the use of salt and chlorine.

In the salt tests, sodium chloride was added in amounts of 6.75 lb per 100 gal of sewage. The sewage in this case had a fat content of only 46 ppm. After thorough mixing, followed by a quiescent period of 7 min, the effluent had a fat content of 18 ppm, showing a fat removal of 60.9%, of which 2.2% was represented in the skimmings. Using the raw sewage with a fat content of 46 ppm, adding salt at the same rate, and aerating for a period of 7 min with 0.18 cu ft of air per gallon of sewage, followed with a quiescent period of 7 min, the fat content was reduced to 12 ppm, a reduction of 74%, of which 4.0% was represented in the skimmings.

Chlorine in amounts of 10 ppm applied to sewage containing 90 ppm of fats, followed by a quiescent period of 7 min, reduced the fats in the effluent to 34 ppm, a reduction of 62.2%, of which 0.9% only was in the skimmings. Chlorine in amounts of 10 ppm applied to a sewage containing 91 ppm of fats, followed by aeration for 7 min at the rate of 0.18 cu ft of air per gallon of sewage and a quiescent period of 7 min, reduced the fat content to 35 ppm, a reduction of 61.6%, of which 2.4% was in the skimmings. The addition of 46.5 ppm of chlorine to a sewage having a fat content of 30 ppm, followed by aeration for 7 min at the rate of 0.18 cu ft of air per gallon of sewage and a quiescent period of 7 min, resulted in a fat removal of 86.7%, of which 2.6% was in the skimmings.

TABLE 12.—SUMMARIZED RESULTS OF EXPERIMENTS

Plus salt[g]	1	7	46	18	60.9	233	2.2	..	..	...	...	3,600	7,500	....
Plus chlorine[h]	2	7	90	34	62.2	466	0.9	..	..	...	...	...	...	....
Aeration[i]	1	7	30	4	86.7	217	2.6	..	..	...	...	...	...	0.22
Plus chlorine[j]	2	7	91	35	61.6	466	2.4	..	..	...	...	...	...	0.18
Plus salt[k]	1	7	46	12	74.0	283	4.0	..	..	...	...	3,600	6,800	0.18

[a] Chlorides. [b] Fill-and-draw sedimentation. [c] Determined in only two runs. [d] Aeration followed by sedimentation. [e] Continuous flow, with skimming baffle. [f] Excluding certain preliminary runs. [g] Sedimentation with 6.75 lb (per 100 gal of sewage) of common salt added. [h] Sedimentation with 10 ppm of chlorine. [i] Sedimentation before and after aeration, with 46.5 ppm of chlorine added. [j] Sedimentation after aeration, with 10 ppm of chlorine added. [k] Sedimentation before and after aeration, with 6.75 lb of salt per 100 gal of sewage added.

The results of the analyses of the samples collected during these experiments are shown in Table 12 and confirm the results of the experiments made on sewage discharged into Boston Harbor, in that the additional amount of removal of fats by aeration did not appear to warrant the addition of aeration to plain sedimentation of the sewage without further treatment for the removal of fats.

Harvey F. Ludwig,[5] **Jun. Am. Soc. C. E.**—A comprehensive review of the grease problem in sewage treatment is presented in this paper. The authors have necessarily limited their discussion of new analytical procedures for the determination of grease; but they do emphasize that there is considerable current interest in the possibility of revising and improving the old standard methods procedure. The writer recognizes that detailed discussions of the various analytical operations making up the proposed new procedures are of interest chiefly to chemists. However, a brief consideration of the fundamental principles involved in these methods should be of considerable interest to the engineer. Such consideration promotes an understanding of the basic characteristic properties and nature of greasy substances, an understanding obviously prerequisite to an intelligent solution of an engineering grease-disposal problem.

Considerable confusion exists in the literature dealing with the analytical determination of grease, and perhaps most of this arises from the lack of an exact definition of just what the term "grease" should include. Some have questioned, for example, that both organic derivatives (lard, butter, soaps, etc.) and mineral derivatives (kerosene, fuel oils, etc.) should be included; others suggest differentiation between "greases" and "oils," according to whether they are solid or liquid at room temperature. Again, a purely theoretical definition of grease on the basis of chemical constituents leads to confusion because certain substances included by such definition have little or no grease-like qualities. Further, such a variety of substances of greatly varying properties have some grease-like qualities that it is obviously impossible to devise a single test that will recover them all.

What interests the sanitary engineer are those substances which are likely to occur in appreciable quantities in domestic or industrial wastes and which will be of sanitary significance—that is, those substances the particular properties of which are important in sewage treatment and disposal practice. "Substances of sanitary significance" again include a multitude of substances of multi-varied properties. These substances generally have one property in common, however, in that they tend to be removed from suspension and to agglomerate, usually at the surface of the medium (hence their "sanitary significance") in which they were originally dispersed in colloidal state. The writer is of the opinion that this property should form the basis of the accepted method of grease determination; and, further, that having adopted such a method, grease should be defined thereafter as just those substances which are recovered by the method.

The old standard methods (1) procedure for determination of grease consists essentially of strongly acidifying the sample with hydrochloric acid, evaporating the sample to dryness, and then extracting the grease from the dry residue with some solvent such as chloroform or petroleum ether. A Soxhlet apparatus is generally used for making the extraction. The procedure is based on the following assumptions: (1) The operation of acidification converts any non-solvent-soluble greases (calcium and magnesium soaps) to solvent-soluble greases (hydrogen soaps or fatty acids); and (2) the operation of evaporating the sample to dryness (which conveniently removes the water, leaving a dry residue on which the extraction is easily made) does not appreciably alter the state or nature of the grease materials in the system.

---

[5] Asst. San. Engr., U. S. Public Health Service, Atlanta, Ga.

Various investigators (9) (33), particularly Messrs. Pomeroy and Wakeman (34), recently have made a critical study of the standard methods procedure, and have discovered that numerous errors result from the operation of evaporating to dryness, because changes in state do occur. These changes may be classified, according to Messrs. Pomeroy and Wakeman, as follows: (*a*) Volatilization of grease; (*b*) reversion of fatty acids to insoluble soaps; (*c*) production of ether-soluble matter (from combined fatty acid radicals without greasy characteristics, as egg yolk); and (*d*) treatment of oils by oxidation and polymerization. Messrs. Pomeroy and Wakeman subsequently devised a novel "wet extraction" procedure (similar to that commonly used in analysis of oil-field wastes and of milk) which eliminates the troublesome evaporation operation. The solvent is added directly to the acidified sample, and the entire mass is shaken thoroughly. After the solvent separates from the remainder of the medium (special technique may be necessary to induce this separation), it is withdrawn, filtered, and evaporated, leaving the residue to be weighed. By this procedure the aforementioned errors are largely eliminated. It should be noted, however, that in both the standard methods procedure and in the Pomeroy-Wakeman method, all of the solvent-soluble materials originally present are recovered, regardless of their grease-like qualities or sanitary significance.

While employed as engineering assistant for the East Bay Cities Sewage Disposal Survey (35), the writer, under the direction of Charles Gilman Hyde, Harold Farnsworth Gray, and A. M. Rawn, Members, Am. Soc. C. E., developed a procedure (33) based on the tendency of grease materials to be removed from suspension and to collect on the surface. This procedure, again an adaptation (being commonly used in soap chemistry), has been called the "boiling-chilling" procedure by the writer, because these two operations are of basic importance. Essentially, the method comprises acidifying the sample, boiling for a few minutes, chilling in the refrigerator (overnight), filtering, drying the filter paper and retained solids, and extracting the grease from these with a suitable solvent, either directly or by means of a Soxhlet. The operation of boiling serves a dual function: (1) To insure complete conversion of insoluble soaps to soluble fatty acids (it is the experience of soap chemists that, in a cold process, conversion is incomplete even under highly acid conditions); and (2) to concentrate the grease in a surface layer or in surface globules (if desired, a large part of the underlying liquid may be drawn off at this point). The operation of chilling serves to congeal the grease globules so that they may be separated later from the system by the operation of filtration. Any solvent-soluble materials which are present in the liquid drawn off after boiling or which are not retained on the filter paper during filtration thus will not appear in the final grease residue.

Messrs. Okun, Hurwitz, and Mohlman (9) subsequently tested this procedure, and developed an improved technique by utilizing certain inert substances to increase mechanically both the rate of filtration of the chilled liquid and the rate of extraction of grease from the dry retained solids. It is interesting to note that the method of grease determination tentatively approved by the Committee on Research of the Federation of Sewage Works Associations in its recent report (36) is the aforementioned boiling-chilling procedure, as improved by Messrs. Okun, Hurwitz, and Mohlman, the final extraction being made in a Soxhlet apparatus with either petroleum ether or hexane.

The question as to which solvent is best suited for extracting the grease from the dry retained solids is a problem in itself. Here again the question of just what is included in the term "grease" is pertinent. The best solvent would be that which most nearly extracts these substances to the exclusion of others. Messrs. Pomeroy and Wakeman have studied the extracting properties of a number of solvents, and recommend hexane as extracting a minimum of non-grease materials and yet having sufficient solvent properties to extract most of the commonly recognized greases.

W. S. MAHLIE,[6] ESQ.—For years sanitary engineers have accepted the fact that there is grease in sewage and that it hinders plant operation. There have been a number of instances in which grease was considered a factor in plant design, but by and large it was not given a very intensive study, and the paper, therefore appears at an opportune time. The question of sewage treatment at army cantonments has focused some attention on this grease problem. Considering the large percentage of grease in raw or primary sludge, it is rather surprising that more work has not been done on the effects of grease in sludge digestion. Messrs. Fales and Greeley comment on the lack of a more standardized method of grease determination. The latest edition of "Standard Methods" contains reference to this subject. The authors are to be complimented on their excellent paper, particularly the part dealing with the methods of grease removal.

DENIS DICKINSON,[7] ESQ.—The question as to which solvent should be used for the determination of grease in sewage is associated closely with the definition of "grease." If the determination is made in order to estimate the difficulties that may arise in the purification of the sewage and the subsequent disposal of the sludge, then there would appear to be sufficient reason for the adoption of chloroform as the solvent, since it is affirmed that this liquid also extracts resinous substances that are likely to be more difficult to break down biologically than the less complex fatty acids. Especially does this apply to those cases in which disposal is left to auto-purification in the sea or in a water course. On the same grounds, chloroform should be adopted for testing the efficiency of any grease removal plant. On the other hand, if it is desired to assess the practicability of grease recovery, then a more selective solvent is preferable.

It is interesting to note that the ratio of the grease as determined by chloroform to that determined by petroleum ether is frequently constant for sludges from any one sewage, although the data available are not sufficient to justify any generalization on this point. It would appear that there is much to be learned from a study of the characteristics of the greases extracted by the various solvents.

---

[6] Chemist in Chg. of Water and Sewage Purification, Fort Worth, Tex.

[7] Campden, Gloucester, England; formerly Asst. Chemist, Stockport (England) Sewage Works.

The recovery of grease has been the practice at several works in England for many years, and there are other cases where floating fat is skimmed off (usually by scoops), drained, and sold for the manufacture of wagon grease, etc. The process for the recovery of grease by solvent extraction of the sludge has a further advantage in that the sludge is finally grease-free and weed-free, all seeds having been destroyed during the extraction process (37). The latter is a very important point as it increases considerably the market value of the sludge as a fertilizer.

The practice of burying grease, which is mentioned in the paper, cannot be condemned too strongly, as it is to be feared that in many cases it merely defers the day on which final disposal must be undertaken.

A very large amount of grease is often discharged from slaughterhouses and meat products factories. Much of this can be eliminated by intelligent recovery at the factory. There is a tendency to make factory grease-traps too small; wherever possible they should be of a size such that the intermittent discharge of hot effluent cannot melt and emulsify the fat which normally floats on the surface at the outlet end of the trap.

CHARLES R. VELZY,[8] M. AM. SOC. C. E.—A comprehensive description of the general problems resulting from grease in sewage is presented in this paper, which includes methods of grease determination and removal, the effect upon receiving waterways, and a brief statement regarding methods of disposal. In sewage treatment works, grease disposal is always a problem to the operator. Its magnitude depends upon the size of the plant, the quantity and characteristics of the grease in the sewage, and the facilities of the treatment plant. Brief comments on the handling and disposal of grease at sewage treatment works are offered.

Although skimming of grease from sedimentation tanks is reasonably successful, the skimming equipment becomes coated with grease, it is unsightly, and there is a tendency to produce odors. The equipment is commonly cleaned by scraping. On larger installations special cleaning equipment using a combination of steam and a cleaning compound may be used effectively and with a saving of labor. Frequent cleaning will keep the equipment in satisfactory condition.

After grease has been removed from skimming tanks or sedimentation tanks, it must be transported to the point of disposal. In small plants this can be done by hand. In large plants pumping is probably the most satisfactory method. The difficulties involved result from the characteristic of grease to stick to whatever it comes in contact with, and from the presence of floating trash which comes off with the grease. This combination defies screening, tends to clog pipes and pump valves, and forms a stiff mat when allowed to stand.

Although these conditions cannot be eliminated, a number of things can be done to minimize the difficulties. Trash can be reduced by good screening of raw sewage. Grease can be kept more or less liquid by moving it frequently with sufficient water, using jets or sprays if necessary.

---

[8] Asst. Engr., Greeley & Hansen, Norfolk, Va.

In some cases grease will coat the interior of piping through which it flows to such an extent as to increase friction head greatly and necessitate removal. This has occurred at the Buffalo, N. Y., plant and there the application of steam inside the sludge line has kept the line open. It has been necessary to apply steam at intervals of from four to six months. It has been introduced through an injector with water so that the grease is actually melted and removed by hot water. Temperatures of approximately 180° F have been required.

The final disposal of grease will vary with the size of the treatment plant and other conditions. In the small plant where grease is handled manually it can be buried. In the moderate size plants it is sometimes piped to low areas where it is drained and burned. It is common practice to pump it with sludge to digestion tanks. This has the advantage of reducing the quantity, as some types will digest, and also adding to the amount of gas produced. Some grease, however, does not digest, or at least is very slow to digest, in which case it accumulates in the top of the digestion tank. If the accumulation becomes several feet thick, it tends to form a stiff mass, and takes up volume in the tank needed for digestion. This mass of floating material consists of trash with varying proportions of grease and is frequently called scum. If it is of excessive depth, it may become necessary to remove it. If the treatment plant employs incineration for sludge disposal, the obvious procedure is to burn the grease.

There are at least two problems involved in this method of disposal. One is that of handling the grease in this condition and the other is the control of temperature in the incinerator. At Buffalo the scum or grease in the sludge tanks is softened with a spray of supernatant liquor until it will flow and can be pumped. It is then drawn off and mixed with sludge for filtering and incineration. Temperature in the incinerator is controlled by regulating the the proportion of scum and sludge.

In general, problems of handling and disposing of grease must be solved at each sewage treatment plant according to the facilities of the plant and the characteristics of the grease obtained at the plant. Some procedures that have been used with varying degrees of success have been indicated. Grease in sewage, from the standpoints of determination, removal, handling, and disposal, constitutes one of the problems of sewage treatment requiring continued study and research.

F. M. DAWSON,[9] M. AM. SOC. C. E.—In discussing the various methods of grease removal from sewage, the authors made brief mention of removing grease at the source of the sewage by use of interceptors. The writer believes that this method of grease removal merits greater emphasis and consideration than hitherto it has received. This is especially true at present, when it is so vital to save all greases and oils. Naturally, reclaimed grease and oil will be in the best condition for further use if they are removed from sewage as soon as possible.

---

[9] Dean and Prof. of Eng., Univ. of Iowa, Iowa City, Iowa.

The common type of grease interceptor has not proved entirely satisfactory in the past, owing to the fact that proper consideration was not given to its design, installation, and cleaning. Hitherto a fixture was installed frequently because some code or regulation required it, and then it was more or less forgotten. However, the basic principle of separating the grease from the water as close to the source as possible is sound. All that was lacking was good engineering in the design and installation of interceptors, and proper maintenance once they were installed.

Contrary to popular belief, the grease is not separated from the incoming waste water, as a result of a reduction in temperature as the water flows through. The grease must be separated in a liquid state since sufficient time is not available for cooling, and also since the temperature of the interceptor is almost always, when in operation, above the congealing temperature of grease. The separation is obtained by securing a proper reduction in velocity of the entering water by use of baffling and by preventing the occurrence of large-scale turbulence. Proper separation depends mainly upon the density difference between the grease and the water. Well-designed interceptors will maintain an average efficiency of 90% for a flow rate equal to 1 gal per min for each 1.0 to 1.5 gal of interceptor capacity. The proper design of interceptors, however, involves the application of considerable experience with, and knowledge of, fluid flow. It is well known that the general problem of separating fluids of different densities is one of importance in many manufacturing plants. The particular case of grease and water is in principle little different from many others, but it is greatly complicated by the many types of wastes carried from the kitchen sink or other sources of waste water.

The government is installing commercial-type interceptors in the kitchens of all cantonments and many other army and navy establishments. To insure that the interceptors will perform properly, each type should have a laboratory test certificate. The Iowa Institute of Hydraulic Research at the University of Iowa, in Iowa City, in cooperation with the Office of the Chief of Engineers and manufacturers of grease interceptors, has developed a laboratory-test procedure and a rating method which indicate quite well the field performance of interceptors. By this procedure interceptors are rated according to the rate of flow, in gallons per minute, which they can handle and still retain, on an average, 90% of the incoming grease. From tests on a great many interceptors, it was decided also that, for the stated flow rate, an interceptor should maintain an average efficiency of 90% up to a grease-retaining capacity equal, in pounds, to twice the flow rate in gallons per minute. Thus, a 25-gal-per-min interceptor should maintain an average efficiency of 90% with a grease capacity of 50 lb.

It is hoped that the war needs for grease and oil will emphasize the many advantages of separating grease and oil at the source, and thus interest more hydraulic and sanitary engineers in the proper design and installation of grease and oil interceptors. All restaurants, hospitals, hotels, and similar types of commercial kitchens should have interceptors near their sinks. For the ordinary restaurant kitchen sink, the flow-rate capacity of any interceptor should not be below 15 gal per min, and preferably not below 20 gal per min. Regular cleaning, at least once a week, is of prime importance.

ALMON L. FALES[10] AND SAMUEL A. GREELEY,[11] MEMBERS, AM. SOC. C. E. —Mr. Weston's discussion of this paper is the result of a large amount of analytical work and experimentation based on a forward looking conception of the problem in Boston Harbor. The data presented illustrate the elusiveness of the grease problem. Table 8, for instance, indicates a near-maximum percentage removal of fats with a 4-hr detention period. For large installations this is a relatively long period and perhaps was one of the reasons for the experiments in stirring, aeration, return sludge, chlorine, and salt. The discussion indicates a leaning toward plain sedimentation for the removal of fats.

Mr. Ludwig has presented an up-to-date discussion regarding the analytical determination of grease. His statement that the determination of grease in the laboratory should be related to design and operation, and should indicate substances of sanitary significance, is a good suggestion for future consideration. It might be well to realize that often much grease is removed with the sludge as well as with the scum. In general, this discussion prompts the suggestion by the writers that operating records could well be kept in the form of a grease balance in which the grease in the raw sewage would be distributed to the grease recovered in scum and sludge plus the grease in the effluent.

Note is made of the discussion by Mr. Mahlie which prompts the suggestion by the writers that those studying the grease problem should refer to his excellent paper (13).

The discussion by Mr. Dickinson states that the practice of burying grease cannot be condemned too strongly. In the opinion of the writers this statement does not apply to the smaller sewage treatment plants with sufficient adjacent land area for disposal by burial. This is a simple method which avoids some of the operating problems of grease disposal in larger plants.

Such operating problems are well described in the discussion by Mr. Velzy. The removal of greasy scum from sedimentation tanks, the operation of pumps for handling the skimmings, and the operations required to keep scum and sludge discharge pipes free of grease, are typical problems requiring attention in design. The formation of scum in sludge digestion tanks is another operating problem. Such problems are accentuated by the presence of small pieces of trash in the scum and sludge which Mr. Velzy indicates can be reduced by good screening. Another problem discussed by Mr. Velzy is the control of temperature in burning greasy scum. These problems indicate that operating analyses or research studies might include determinations of viscosity, congealing characteristics, and the Btu-content.

Dean Dawson calls attention to the grease interceptor which is a device for removing grease at the source of the sewage. The writers doubt that such a method has general applicability in municipal practice, although the device is applicable at places where relatively large amounts of grease are likely to enter the sewers; as, for instance, garages and large kitchens, such as those at hotels and restaurants. Such interceptors appear also to have a place at the relatively large kitchens of army cantonments. Several municipalities have adopted ordinances requiring installation of interceptors at garages and large kitchens. In general, when the disposal of the intercepted grease is difficult, the maintenance of interceptors requires careful and thorough inspection.

[11] (Greeley & Hansen), Chicago, Ill.

Since February, 1942, when the paper was published in *Proceedings*, considerable progress has been made toward a standard method for the determination of grease in sewage and it may be that the next edition of "Standard Methods for the Examination of Water and Sewage" (1) will present such a method. The war year, however, has tended to retard the accumulation of data, on an operating scale, regarding grease in sewage, effluents, and sludge.

DESIGN OF ST. GEORGES TIED ARCH SPAN

By J. M. Garrelts,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. R. W. Abbett, Jacob Karol, Alexander Dodge, Carlos A. Bejarano, A. A. Eremin, A. M. Freudenthal, C. H. Gronquist, Harold E. Langley, and J. M. Garrelts.

Synopsis

The procedure used to determine the preliminary and final designs for a tied arch bridge is presented in this paper. Although the type of structure is not new, having been used in Europe, it is believed that the design introduces a new type in American practice. The structure differs from the usual tied arch in that the ratio of the moment of inertia of the tie girder to that of the arch rib is approximately 13 to 1. With these relative physical properties, the total bending moment taken by the rib and girder together is divided between these two elements, the major part being resisted by the girder. (The distribution of this bending moment has been discussed elsewhere by Nathan M. Newmark,[2] Assoc. M. Am. Soc. C. E.)

Introduction

The St. Georges bridge (Fig. 1) is designed to carry the DuPont Highway over the Chesapeake and Delaware Canal at St. Georges, Del. It consists of a 540-ft span over the canal flanked on either side by steel plate-girder and rolled-beam approaches, the over-all length between abutments being approximately 4,200 ft. Selection of a suitable type of structure for the main channel span involved both the essential provision for clearance and a solution that would be satisfactory from the esthetic standpoint.

Provision for full clearance below the floor level for the entire span limited the possible types of structure. Studies made by the architect and the engineers resulted in the selection of a tied arch. With this type, it was possible to extend the main line of the approach girders through the tie girder of the arch and thus, through this esthetically dominating line in the design, to give a

Note.—Published in December, 1941, *Proceedings*.

[1] Associate Prof., Civ. Eng., Columbia Univ., and Designing Engr., Waddell & Hardesty, New York, N. Y.

[2] *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 73.

continuity, a feeling of unity, to the entire construction. Further emphasis of this main element of the esthetic composition was secured by designing the arch rib itself relatively thin, making it appear more as a reinforcement for the tie girder than as the main supporting member.

The writer realizes that this basic idea in the esthetics of the structure may be questioned—other approaches were possible—but, after due consideration, this plan of treatment seemed to be the most promising. It is not the purpose of this paper, however, to develop this phase of the St. Georges design in greater detail.

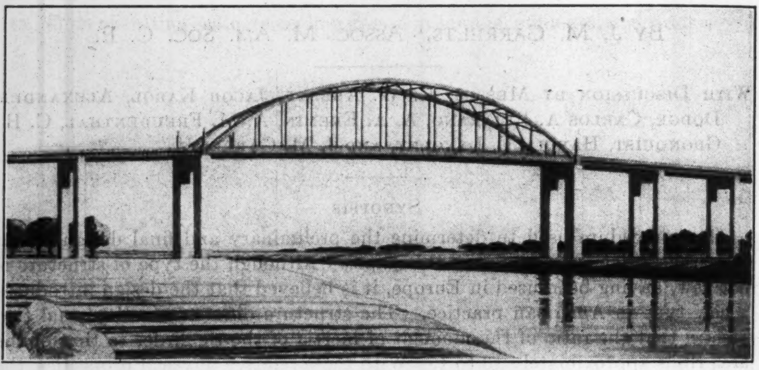

FIG. 1.—ST. GEORGES HIGHWAY BRIDGE

In line with this adopted plan, the tie girder was made the same depth as the approach girders—about 9 ft; and a depth of 3.5 ft was selected for the arch rib. With these dimensions, the tie girder will resist the major part of the bending moments produced by the live load.

Such a structure is multiply indeterminate, and it is the purpose of this paper to outline the method used in arriving at the final design and to describe the completed structure.

NOTATION

The letter symbols in this paper are defined where they first appear and are assembled in the Appendix for convenience of reference.

PRELIMINARY DESIGN

By making some reasonable assumptions which did not introduce an appreciable error in the analysis, it was possible to simplify the problem considerably. In the particular structure being considered, the hangers were rather long and slender, and it was assumed that they would not resist bending moment but would carry only direct stress.

As a first approximation, in the preliminary analysis, it was further assumed that the arch rib resisted no bending moment—that it was subjected only to compression. This assumption implies that the tie girder resists the tension produced in the tie, and also a moment at any vertical section that is equal to the difference between the bending moment due to the external loads and the moment equal to the horizontal component (H) of force in the rib and girder times the vertical distance between the neutral axes of the girder and rib. This can be written as follows (see Fig. 2(a)):

$$M = M' - H\,y \tag{1}$$

in which: H = horizontal component of the rib compression = horizontal component of the tie tension; M = bending moment to be resisted by the tie girder; M' = simple beam bending moment at any vertical cross section A–A (Fig. 2(a)) produced by the external forces. The horizontal component of the rib compression is taken as the redundant. To determine this force H, a statically determinate substitute structure, obtained by cutting the rib at the center C (Fig. 2(b)), is assumed. The principle of virtual work can be used to determine H.

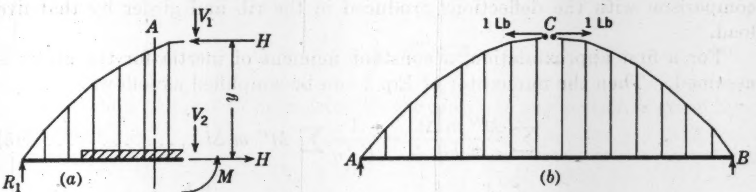

FIG. 2

Let: Δ'_C = relative horizontal displacement of the two cut faces at C, due to the applied load, with $H = 0$; Δ_{1C} = relative horizontal displacement of the two cut faces at C, due to $H = 1$; then

$$H = -\frac{\Delta'_C}{\Delta_{1C}} \tag{2}$$

in which

$$\Delta'_C = \sum \frac{M''\,m\,\Delta l}{E\,I} + \sum \frac{s''\,u\,l}{A\,E} \tag{3a}$$

and

$$\Delta_{1C} = \sum \frac{m^2\,\Delta l}{E\,I} + \sum \frac{u^2\,l}{A\,E} \tag{3b}$$

M'' being the bending moment and s'' the direct stress in any member of the substitute structure ($H = 0$), produced by the applied loads. The symbol m is the bending moment and u the direct stress in any member of the structure due to $H = 1$; l and Δl are the length of any member and an element of length of a member, respectively, used in the summation; E is the modulus of elasticity; A, the cross-sectional area; and I, the moment of inertia of the cross-sectional area of any member.

The formula for H can be written:

$$H = -\frac{\sum \dfrac{M''_G\,m\,\Delta l}{E\,I_G}}{\sum \dfrac{m^2\,\Delta l}{E\,I_G} + \sum \dfrac{u^2\,\Delta l}{A_G\,E} + \sum \dfrac{u^2\,\Delta l}{A_R\,E}} \tag{4}$$

in which A_G and I_G are the area and the moment of inertia of the cross section of the girder, respectively, and A_R is the area of the rib.

To be consistent with the assumption that compression alone acts in the rib, the hanger loads are assumed to be equal, and the load points or points of intersection of the hangers and rib are selected so that they lie on a parabolic curve.

The effects of any deformations in the hangers are neglected. This approximation introduces very small error because the hangers can be fabricated so that they will have the correct length under dead load; and at any section where the moment is appreciable the elongation of a hanger due to live load is small in comparison with the deflections produced in the rib and girder by that live load.

For a first approximation, a constant moment of inertia for the girder is assumed. Then the numerator of Eq. 1 can be simplified as follows:

$$\sum \frac{M'' \, m \, \Delta l}{E \, I_G} = \frac{1}{E \, I_G} \sum M'' \, m \, \Delta l \, \dots\dots\dots\dots\dots (5)$$

Due to $H = 1$, the load in the hangers is equivalent to $\frac{8\,h}{L^2}$ per unit of length. Then

$$m = -\frac{4\,h}{L}\,x + \frac{8\,h\,x^2}{L^2\;2} = -\,y \, \dots\dots\dots\dots\dots (6)$$

using the coordinates indicated in Fig. 3. For the girder $u = 1$, and for the rib $u = 1 \sec \alpha$.

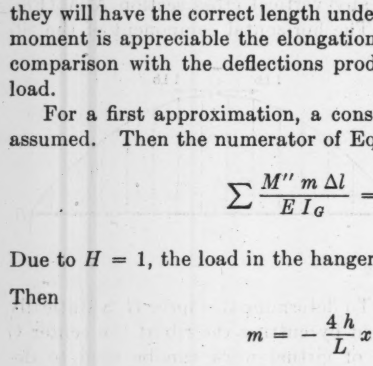

FIG. 3

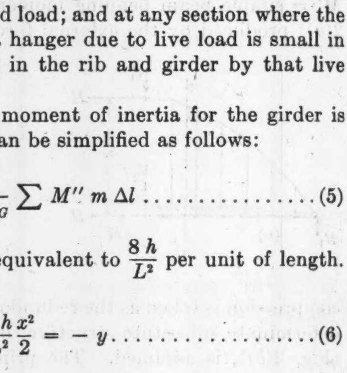

FIG. 4

The summations indicated in Eq. 4 reduce to the following values:

$$\sum \frac{m^2 \, \Delta l}{E \, I_G} = \frac{1}{E \, I_G} \sum y^2 \, \Delta l = \frac{8}{15} \frac{h^2 \, L}{E \, I_G} \dots\dots\dots\dots (7a)$$

$$\sum \frac{u^2 \, \Delta l}{E \, A_G} = \frac{1}{E \, A_G} \sum u^2 \, \Delta l = \frac{L}{E \, A_G} \dots\dots\dots\dots (7b)$$

and

$$\sum \frac{u^2 \, \Delta l}{E \, A_R} = \frac{1}{E \, A_R} \sum \left(1 \times \frac{\Delta l}{\Delta x} \right)^2 \Delta l = \frac{L + 8 \frac{h^2}{L}}{E \, A_R} \dots\dots\dots (7c)$$

In Eq. 7c, A_R is assumed to be constant for this preliminary analysis.

From Eq. 4:

$$H = \frac{\int M'' \, y \, dl}{\frac{8}{15} h^2 L + \frac{I_G L}{A_G} + I_G \frac{\left(L + 8 \frac{h^2}{L}\right)}{A_R}} \qquad (8a)$$

The denominator of Eq. 8*a* depends only on the dimensions of the structure, and an examination of the terms indicates that the first term is large in comparison with the other two. Using only the first term, a simplified formula for *H* is obtained:

$$H = \frac{15}{8 \, h^2 \, L} \int M'' \, y \, dl \qquad (8b)$$

The bending moment to be resisted by the girder at any section is given by the equation

$$M_G = M'' - H \, y = M'' - \frac{15}{8} \frac{y}{h^2 \, L} \int M'' \, y \, dx \qquad (9)$$

Using Eq. 8*b*, influence values for *H* were determined by placing a unit load at each panel point in turn, from which the maximum values for the direct stresses in the rib and girder were computed. Influence values for M_G due to unit load at each panel point were computed, using Eq. 9, and with the aid of these coefficients the maximum live-load moments in the girder were determined. With these preliminary direct stresses and moments, sections were determined which were used as a basis for making the more exact analysis.

The total bending moment *M*, which was assumed to be resisted entirely by the tie girder in the preliminary analysis, is actually taken by both the rib and girder. It is necessary then to develop a method for determining the proportion of this total moment taken by the rib and by the girder.

In order to proportion this bending moment at any section between the arch rib and tie girder, the relation between the vertical components of deflection of the rib and girder at any section will be used.

At any point *P* in the arch rib (Fig. 4), let *v* represent the component of deflection along a normal to the arch rib curve at that point. From the differential equation for the deflection of a curved beam, the normal component of deflection *v* is

$$\frac{d^2 v}{dl^2} + \frac{v}{\rho^2} = \pm \frac{M_R}{E \, I_R} \qquad (10a)$$

in which *dl* is an element of length of the arch rib; ρ is the radius of curvature of the rib at point *P*; M_R is the moment taken by the rib; and I_R is the moment of inertia of the rib.

The second term of Eq. 10*a* can be neglected without appreciable error, and the equation reduces to

$$\frac{d^2 v}{dl^2} = \pm \frac{M_R}{E \, I_R} \qquad (10b)$$

The vertical component of the deflection of the arch rib is equal to the vertical component of v, if the tangential component of deflection at P (which is small) is neglected; then

$$\eta = v \cos \alpha \text{ .... } (11)$$

in which η is the vertical component of v, and α is the angle between the tangent at P and the x-axis.

The first term of Eq. 10b can be replaced by an expression involving η, x, and α as follows: From Eq. 11—

$$\frac{d\eta}{dl} = \frac{dv}{dl} \cos \alpha - v \frac{d\alpha}{dl} \sin \alpha; \qquad \text{and} \qquad \frac{d^2\eta}{dl^2} = \cos \alpha \frac{d^2v}{dl^2}$$

$$- 2 \frac{dv}{dl} \frac{d\alpha}{dl} \sin \alpha - v \frac{d^2\alpha}{dl^2} \sin \alpha - v \left(\frac{d\alpha}{dl} \right)^2 \cos \alpha$$

$$= \cos \alpha \frac{d^2v}{dl^2} - 2 \frac{dv}{dl} \frac{1}{\rho} \sin \alpha + \frac{v}{\rho^2} \frac{d\rho}{dl} \sin \alpha - \frac{v}{\rho^2} \cos \alpha \text{ .... } (12)$$

Neglecting the last three terms of Eq. 12:

$$\frac{d^2v}{dl^2} = \sec \alpha \frac{d^2\eta}{dl^2} \text{ (approximately) .... } (13)$$

Using $dx = ds \cos \alpha$, Eq. 13 reduces to

$$\frac{d^2v}{dl^2} = \cos \alpha \frac{d^2\eta}{dx^2} \text{ .... } (14a)$$

or

$$\pm \frac{M_R}{E\,I_R} = \cos \alpha \left(\frac{d^2\eta}{dx^2} \right) \text{ (approximately) .... } (14b)$$

For the girder (Fig. 4)

$$\pm \frac{M_G}{E\,I_G} = \frac{d^2y'}{dx^2} \text{ .... } (15)$$

in which M_G is the moment taken by the girder, and I_G is the moment of inertia of the girder.

The total moment M_T is equal to $M_R + M_G$; and, neglecting the change in lengths of the hangers, $\frac{d^2\eta}{dx^2} = \frac{d^2y'}{dx^2}$. Therefore, using Eqs. 14b and 15:

$$M_T = M_G \frac{I_G + I_R \cos \alpha}{I_G}$$

Then

$$M_G = M_T \left(\frac{I_G}{I_G + I_R \cos \alpha} \right) \text{ .... } (16a)$$

and

$$M_R = M_T \left(\frac{I_R \cos \alpha}{I_G + I_R \cos \alpha} \right) \ldots\ldots\ldots\ldots\ldots (16b)$$

The formula for H becomes

$$H = \frac{\sum \frac{M' \, m \, \Delta l}{I_{tr}}}{\sum \frac{m^2 \, \Delta l}{I_{tr}} + \sum \frac{\Delta l}{A_G} + \sum \frac{\sec^2 \alpha \, \Delta l}{A_R}} \ldots\ldots\ldots\ldots\ldots (17)$$

in which $I_{tr} = I_G + I_R \cos \alpha$.

The Final Design

The span of the arch is 540 ft, with fifteen panels at 36 ft, and the rise is 100 ft. To perform the summations indicated in Eq. 17 the structure was divided into sections, each having a length equal to a panel length. With this equation, influence lines for H were determined as follows:

Load at panel point	Value of H
1	0.2358
2	0.4595
3	0.6625
4	0.8372
5	0.9772
6	1.0772
7	1.1300

The tie girder, instead of being straight, follows the vertical curve of the roadway, and the factor m in Eq. 17 is given by $m = y' - y$, in which y is the ordinate to the arch rib and y' is the ordinate to the girder.

The moment M_T to be resisted by the girder and arch rib together is given by the expression (see Eq. 1)

$$M_T = M' - H(y - y') \ldots\ldots\ldots\ldots\ldots (18)$$

in which M' is the simple beam bending moment. The curves of Fig. 5 show the influence lines for M_T as computed for the final design sections. The maximum live-load moment was computed for the final design sections, and the proportionate part taken by both the rib and the girder determined in accordance with Eqs. 16. Shears were calculated but were found to be very small.

The dead load used for design was 15.1 kips per ft of length of bridge and the H-20 live load was used. The dimensions of the structure are shown in Fig. 6 and an example of the arrangement of the design stresses and sections is shown in Figs. 7 and 8. A dead-load moment of 500 ft-kips was included in the stresses at each point to allow for the fact that there may be some dead-load moment in the structure after it is under full dead load.

The total weight of steel in the span is 2,166 tons, classified as follows:

Members	Tons
Girders	711
Ribs	547
Hangers	123
Bracing	186
Floor beams	210
Stringers	291
Diaphragms and railing	98

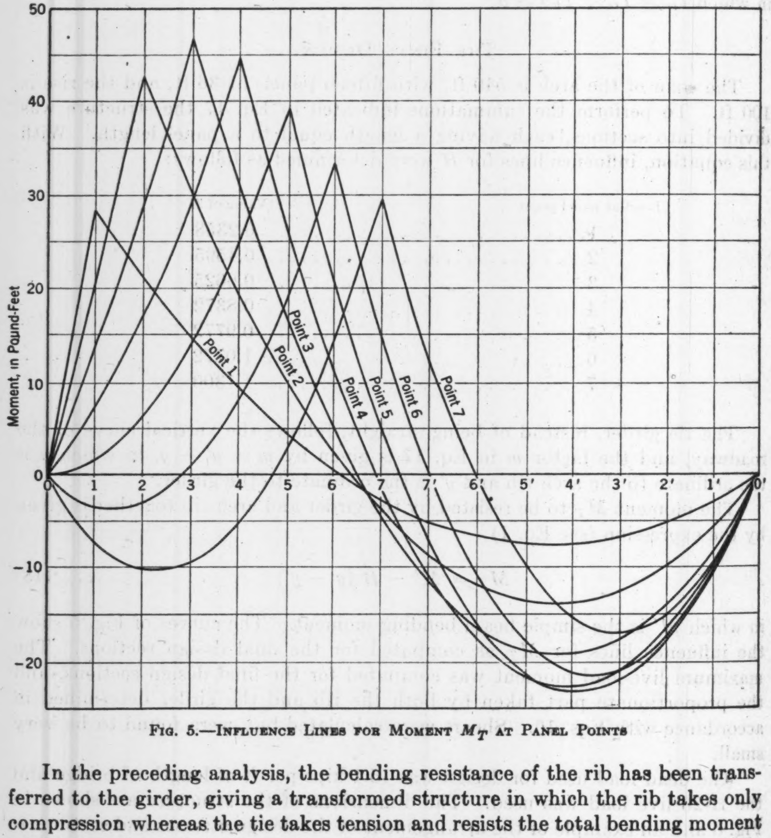

Fig. 5.—Influence Lines for Moment M_T at Panel Points

In the preceding analysis, the bending resistance of the rib has been transferred to the girder, giving a transformed structure in which the rib takes only compression whereas the tie takes tension and resists the total bending moment with a transformed moment of inertia. Theoretically, it would also be possible to analyze the structure as one in which the bending resistance of the girder is transferred to the rib. This would result in a transformed structure in which the tie girder would take only tension, while the rib would take compression

Fig. 7.—Example of the Arrangement of Data: Design Stresses and Sections

The proper procedure in any case should be that which more nearly agrees with the behavior of the structure. In the St. Georges bridge, the girder resists approximately 93% of the total bending moment and the rib 7%, so that the procedure used is more nearly in agreement with the structural action which the analysis indicates.

The tie girder and arch rib are both cambered for full dead load. However, the dead-load moment in the tie girder will not be zero unless the span is riveted up in the position it will assume under full dead load. Due to the fact that the riveting up will be done before the concrete deck is poured, some method of closing is necessary which will induce a moment in the girder at the time of riveting to neutralize the moment produced by the additional dead load of the floor slab. This will be accomplished by closing the span on a pin in the tie girder, at the center of the span located above the center line of the girder a distance sufficient to develop the predetermined moment. By riveting this joint up in the distorted position, the desired result will be obtained.

FIG. 8.—EXAMPLE OF ARRANGEMENT OF DATA: CHARACTERISTICS OF HANGERS

A model analysis was made of the St. Georges arch by graduate students at Princeton University at Princeton, N. J., under the direction of Prof. E. K. Timby, Assoc. M. Am. Soc. C. E. The "Beggs Deformeter" was used to measure the strains in a celluloid model. Influence values for both the direct stress and the moment computed from the deformeter measurements were in close agreement with those calculated by the theoretical analysis. The results of these tests serve to confirm the correctness of the assumptions made in the design analysis.

ACKNOWLEDGMENTS

The St. Georges bridge is a project of the Corps of Engineers of the U. S. Army under the supervision of Lt.-Col. Harry B. Vaughan, Jr., M. Am. Soc. C. E., district engineer of the Philadelphia District.

Maurice N. Quade, M. Am. Soc. C. E., is in charge of the project for the firm of Parsons, Klapp, Brinckerhoff and Douglas; Alfred Hedefine, Assoc. M. Am. Soc. C. E., is in charge of the design of the arch span for the firm of Waddell and Hardesty; and Aymar Embury II, M. Am. Soc. C. E., is the consulting architect.

APPENDIX

NOTATION

The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering, and Testing Materials, prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:[3]

A = area of cross section:
  A_G = area of girders;
  A_R = area of rib;
E = modulus of elasticity;
H = horizontal component of rib compression and tie tension;
h = rise of the arch rib;
I = moment of inertia:
  I_G = of girder;
  I_R = of rib;
L = length of span;
l = length of panel, or other structural member; Δl = a segment of l;
M = bending moment to be resisted by the tie girder:
  M' = simple beam moment at any vertical cross section (section A–A, Fig. 2(a)) produced by the external forces;
  M'' = moment in any member of a substitute structure;
  M_G = moment to be resisted by the girder at any section;
  M_R = moment resisted by the rib;
  M_T = total moment;
m = bending moment in any member of a structure due to $H = 1$;
s'' = stress in the substitute structure ($H = 0$), produced by the applied loads;
u = direct stress in any member of a structure, due to $H = 1$;
v = normal component of the deflection;
x = horizontal coordinate distance to any point on arch rib or girder;
y = vertical ordinate to any point on arch rib;
y' = vertical ordinate to any point on tie girder;
Δ = total deformation = relative horizontal displacement of two cut faces:
  Δ' = displacement when $H = 0$;
  Δ_1 = due to $H = 1$;
η = vertical component of v;
α = slope of the arch rib at any point = angle between the tangent at point P, and the x-axis;
ρ = the radius of curvature of the rib at point P.

---

DISCUSSION

R. W. Abbett,[4] **M. Am. Soc. C. E.**—A clear and concise statement of the basic theory of the design of an unusual type of bridge superstructure is presented in this paper. The fact that the principles of mechanics that are involved are not new to structural engineers does not detract from the usefulness of the explanation of their unique application. In all probability, however, the author's greatest contribution lies in the original procedure that he has developed for the preliminary design. The dimensioning of a statically indeterminate structure to initiate a stress analysis is a critical matter as far as labor and time are concerned, and the systematic procedure now available will be most helpful to future designers of similar arches.

As far as the writer is aware, the St. Georges arch represents the first of its type in the United States, but several such structures were built in Europe before the beginning of the present war. It has certain definite architectural advantages when combined with deep girder approach spans, such as were possible and economical in this instance. A great deal of consideration was given to the appearance of the bridge because of its dominating location on Delaware's main highway.

As to the economy of the design, a comprehensive study of the cost of the arch span was made in comparison with other possible layouts for the St. Georges crossing, but few data are available for other span lengths. For spans of the order of 540 ft, the cost was estimated to be about the same as that of a Warren-type simple truss of the same length, and when combined with the girder approach spans this layout produced the least over-all cost of any considered for the high-level design. A low-level crossing with a vertical-lift main span, similar to the Buzzards Bay Bridge over Cape Cod Canal promised to be the least expensive of all, but this design was rejected by the client because of the heavy traffic on DuPont Highway and because of the frequent openings required for ship passages through the canal. A through cantilever truss and a self-anchored suspension bridge were considered for the main span. The costs of these two types were about equal and considerably greater than that of the arch or simple truss, principally because of the economy of short, simple-girder, flanking spans in lieu of the relatively heavy and expensive anchor spans required for both the cantilever and the suspension type. A tunnel was investigated and found to cost more than all bridge types. This was still the case when a two-lane tunnel was compared with four-lane bridges.

The fact that all piers were built on dry land effected the economy of the design in that substructure costs were reduced and shorter approach spans were possible in accordance with the economic principle of balancing the cost of substructure against cost of superstructure.

Jacob Karol,[5] **Assoc. M. Am. Soc. C. E.**—An interesting description of the design of a tied arch span is contained in this paper. This type of structure contains approximately the same amount of metal as a simple truss span carrying the same loads, and is certainly more pleasing in appearance than any type of through truss. Hence, it should find increasing use in locations where esthetic considerations are of some importance.

[5] Structural Engr., Airplane Div., Curtiss-Wright Corp., Lambert Field, Robertson, Mo.

The writer wishes to indicate certain simplifications in the preliminary design procedure. If the integration is performed in Eq. 8*b*, the expression for the influence line for H becomes

$$H = \frac{5\,l}{8\,h}\,(k^4 - 2\,k^3 + k) \qquad (19)$$

in which k is the proportionate distance from the left end of the span to the unit load. Table 1 shows the comparison between the values of H from this formula and the final values of H given by the author.

TABLE 1.—COMPARISON OF VALUES OF H

Load at panel point	By formula	Author
1	0.240	0.2358
2	0.468	0.4595
3	0.674	0.6625
4	0.850	0.8372
5	0.987	0.9772
6	1.080	1.0772
7	1.128	1.1300

Thus, it is seen that a very close approximation to the final influence line for H, and hence to the final direct stresses, can be obtained if only the span length and the center rise are known. Having the influence line for H, influence lines for M may be determined from Eq. 9. It should be assumed, however, that the live-load moments determined from these influence lines represent the total moments resisted by the arch rib and tie girder.

The next step is to determine the division of the total moment between the girder and the rib. The author's procedure, using Eq. 16, requires that the moments of inertia of the rib and the girder be known in advance. However, this division can be obtained approximately if only the depths of the rib and the girder are known. From the flitched-beam concept, the angle changes along the rib are equal to those along the girder (except for the change in length of the hangers, which effect will be neglected). Hence,

$$\frac{M_G\,dx}{E\,I_G} = \frac{M_R\,ds}{E\,I_R} = \frac{M_R\,dx}{E\,I_R\cos\alpha} \qquad (20)$$

from which

$$\frac{M_R}{M_G} = \frac{I_R\cos\alpha}{I_G} \qquad (21)$$

If the sections of the rib and girder are assumed to be proportional to their direct stresses, then

$$A_G = C_1\,A_R\cos\alpha \qquad (22)$$

in which C_1 = the ratio of the unit stresses due to the direct loads in the rib and girder, respectively, $= \frac{f_{R(d)}}{f_{G(d)}}$.

The value of C_1 may be obtained as follows: Assume a value of the fiber stress due to bending in the girder. In the structure under consideration this value is about 8,000 lb per sq in. on the gross section. This value may be determined approximately at a particular section, using the direct loads and moments previously found in the following equations:

$$f_G = \frac{H}{A_G}\left(1 + \frac{2.5\,e}{d_G}\right) = f_{G(d)}\left(1 + \frac{2.5\,e}{d_G}\right)\ldots\ldots\ldots\ldots(23)$$

in which f_G = allowable unit stress in girder on gross section; H = tension due to dead load and live load; $e = \frac{M}{H}$; and M is the moment due to dead load and live load.

Since $f_G = f_{G(b)} + f_{G(d)}$, by substitution in Eq. 23,

$$f_{G(d)} = \frac{f_G\, d_G}{d_G + 2.5\,e}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(24a)$$

and

$$f_{G(b)} = \frac{f_G \times 2.5\,e}{d_G + 2.5\,e}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(24b)$$

For the case presented in the paper, assume that the allowable stress in the girder $f_G = 80\% \times 24{,}000 = 19{,}200$ lb per sq in. on the gross section; also, for the allowable stress in the rib, $f_R = 19{,}400$ lb per sq in. Since the unit stresses in the girder and rib due to bending are approximately proportional to their respective depths,

$$f_{R(b)} = f_{G(b)} \times \frac{d_R}{d_G}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(25)$$

Substituting numerical values, $d_R = 40$ in. and $d_G = 108$ in., and $f_{R(b)} = 8{,}000 \times \frac{40}{108} = 3{,}000$ lb per sq in. Hence, the unit stresses due to direct loads are $f_{G(d)} = 19{,}200 - 8{,}000 = 11{,}200$ lb per sq in. in the girder and $f_{R(d)} = 19{,}400 - 3{,}000 = 16{,}400$ lb per sq in. in the rib, from which $C_1 = \frac{16{,}400}{11{,}200} = 1.46$. Substituting in Eq. 22, $A_G = 1.46\, A_R \cos\alpha$.

The moments of inertia of the girder and rib may be written

$$I_G = C_2\, A_G\, d^2_G\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(26a)$$

and

$$I_R = C_3\, A_R\, d^2_R\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(26b)$$

Since the girder and rib are both box sections, assume $C_2 = C_3$ for simplicity. Then

$$\frac{I_R}{I_G} = \frac{C_3\, A_R\, d^2_R}{1.46\, C_2\, A_R\, d^2_G \cos\alpha} = \frac{d^2_R}{1.46\, d^2_G \cos\alpha}\ldots\ldots(27a)$$

and

$$\frac{M_R}{M_G} = \frac{d^2_R \cos\alpha}{1.46\, d^2_G \cos\alpha} = 0.685\,\frac{d^2_R}{d^2_G}\ldots\ldots\ldots\ldots(27b)$$

Substituting numerical values, $\frac{M_R}{M_G} = 0.685 \times \frac{(40)^2}{(108)^2} = \frac{1}{10.6}$; $\frac{M_R}{M_T} = \frac{1}{10.6 + 1} = \frac{1}{11.6} = 8.6\%$; and $\frac{M_G}{M_T} = \frac{10.6}{11.6} = 91.4\%$.

This agrees very well with the distribution indicated by the author. It may be stated that, by assuming $C_1 = 1$, without making any calculations whatever to determine its value, the distribution of the total moment to the rib and the girder is 12.1% and 87.9%, respectively.

Hence, the foregoing procedure results in a preliminary determination of the division of the total moment between the rib and the girder, and of the direct stresses in the rib and the girder, with sufficient accuracy that the sections determined therefrom should be very near the final sections. It is worth emphasizing that these results can be obtained when only the span length, the center rise, and the depths of the rib and girder are known. Having thus obtained sections on which to base an analysis, the final analysis would follow the author's procedure, using Eqs. 16, 17, and 18.

ALEXANDER DODGE,[6] ESQ.—Professor Garrelts undertakes to design a multiply indeterminate structure by a simplified method. A design of this nature is usually very cumbersome, and in practice various short cuts frequently are permitted. However, the introduction of various assumptions by the author, without proof of their correctness, has made his paper inconclusive. The disputable parts of the analysis are as follows:

1. In the preliminary analysis, by assuming that the arch rib has resisted no bending, as well as by omitting the term $\sum \frac{M''_R\, m\, \Delta l}{E\, I_R}$ from Eq. 4, the author assumes that the rib is composed of a number of members pin-connected at the springing and at each hanger point. How the condition of continuity in the structure was finally restored has not been shown.

2. To find the distribution of bending moment between arch rib and girder, their relative deflections were supposed to be used, but the differential equation (Eq. 10*a*) holds true only for a thin curved bar of a constant cross section with circular axis and when subjected to transverse loading only.[7] A small initial curvature makes a great change in the effect of longitudinal forces on the deflection of the arch rib. The correct differential equation for deflection of an arch rib has been published by S. Timoshenko.[8]

The paper does not give full information regarding properties of the structure such as cross section and moment of inertia of the arch rib and the tie girder. Nevertheless, Figs. 6 and 7 give some indications on which the writer bases the following deductions:

The distribution of moment of inertia in an arch rib is probably not very different from that commonly used in practice, variation being proportional to sec α. The average area of tie used in computing deformations is probably about 265 sq in., and the moment of inertia at the crown, I_C, about 48,000 in.^{4} These values will be used in the discussion that follows, as well as the given ratio of tie girder to arch rib (13 : 1). The table of ordinates in Fig. 6 shows that the arch rib is parabolic in shape with a ratio of $\frac{h}{L} = 0.185$.

FIG. 9.—ISOLATED ARCH RIB

Assuming a pin condition at the springing and neglecting rib shortening, the deflection of an arch rib (Fig. 9), at a point q due to H_Δ, is

$$\delta_{qH} = \frac{H_\Delta}{E}\int_A^G y\,\frac{ds}{I}\,m' = \frac{H_\Delta}{E\,I_C}\int_A^G y\,m'\,dx = \frac{H_\Delta\,h\,L^2}{E\,I_C}\,\epsilon \;\ldots\ldots (28)$$

In Eq. 28, $y = \frac{4\,h}{L}\left(x - \frac{x^2}{L}\right)$; $I = I_C \sec \alpha$; I_C = minimum moment of inertia (at the crown); m' = the simple beam bending moment in the arch rib due to a unit vertical load at point q, when $H = 0$; and ϵ = the numerical coefficient of the vertical deflection.

FIG. 10.—COEFFICIENTS OF VERTICAL DEFLECTIONS, ϵ, DUE TO $H = 1$

By Maxwell's Law of Reciprocal Deflections δ_{Hq} = the horizontal deflection at A due to a vertical load P at $q = \delta_{qH}$, or $\delta_{Hq} = \delta_{qH} = \frac{H_\Delta\, h\, L^2}{E\, I_C}\,\epsilon = \frac{P\, h\, L^2}{E\, I_C}\,\epsilon$ provided the horizontal load H_Δ is equal to P.

The horizontal deflection δ_{HH} of the point A due to H_Δ is

$$\delta_{HH} = \frac{H_\Delta}{E}\int_A^G \frac{m_H\, m_H\, ds}{I} = 0.53333\,\frac{h^2\, L\, H_\Delta}{E\, I_C} \ldots\ldots\ldots\ldots (29)$$

in which m_H = the simple beam bending moment in the arch rib due to a unit horizontal load at A.

The deflection of the arch rib at p due to a unit vertical load at q is

$$\delta_{pq} = \int_A^G \frac{M_S\, m'\, ds}{E\, I} - H_q \int_A^G \frac{m_H\, m'\, ds}{E\, I} = \frac{L^3}{E\, I_C}\,(\lambda - \phi) = \frac{L^3}{E\, I_C}\,\eta \ldots (30)$$

in which: M_S = the simple beam moment in the arch rib due to a unit vertical load at q; H_q = the horizontal reaction at the springing due to a unit vertical load at q, for an arch, with fixed pins to prevent horizontal movements; λ = the numerical coefficient of the vertical deflections for an arch acting as a simple beam; ϕ = the numerical coefficient of the vertical deflection due to H_q alone = $H_q\,\epsilon$; and η = the numerical coefficient of the final vertical deflection. Coefficients ϵ, λ, and η are obtained by performing the necessary integrations. The coefficients of deflections were computed by the writer and are recorded in Fig. 10 and Table 2. The inspection of these coefficients will indicate immediately the importance of the longitudinal force (horizontal thrust) on the deflection of the arch rib, as has been stated previously in this discussion.

Deflection of the tie girder, acting as a simple beam, due to a unit vertical load is

$$\Delta = \frac{C'\,L^3}{E\,I_G} = \frac{C\,L^3}{E\,I_C} \ldots (31)$$

in which C = the coefficient of the vertical deflection = $\frac{C'}{13}$ (see Table 2(*c*)). The ratio $\frac{I_G}{I_C} = 13$ is assumed to hold true at the crown.

The behavior of the St. Georges tied arch has been studied by means of coefficients of deflections on the assumption that five hangers only were acting, each hanger having a gross area of 35 sq in. The unknowns are a horizontal thrust, H, and five hanger interactions, assumed to be all tensions, as shown in Fig. 11. The summary of deflections for these conditions is given in Table 3. The subscript notations in this table refer—first letter, to the point on the structure, and second letter, if shown, to the point at which a force is acting. For example, δ_{BD} is a deflection of the arch rib at point B due to a load acting at point D.

For a unit load of 1,000 lb at $k = 0.5$, the deflection equations in terms of deflection coefficients (the term $\frac{L^3}{E\,I_C}$ is dropped from all following computations) for points, B, C, and D, respectively, will be as follows:

$$\begin{aligned}&- 0.220 + 0.6951\,R_B + 0.6401\,R_C - 0.220\,R_D - 0.6932\,R_E - 0.3716\,R_F\\&\quad + 0.208\,R_B + 0.449\,R_C + 0.474\,R_D + 0.346\,R_E + 0.126\,R_F = 0 \quad (32a)\end{aligned}$$

$$\begin{aligned}&- 0.043 + 0.6401\,R_B + 1.2486\,R_C - 0.043\,R_D - 1.1514\,R_E - 0.6932\,R_F\\&\quad + 0.449\,R_B + 1.131\,R_C + 1.269\,R_D + 0.946\,R_E + 0.346\,R_F = 0 \quad (32b)\end{aligned}$$

and

$$\begin{aligned}&+ 0.4882 - 0.220\,R_B - 0.043\,R_C + 0.4882\,R_D - 0.043\,R_E - 0.220\,R_F\\&\quad + 0.474\,R_B + 1.269\,R_C + 1.603\,R_D + 1.269\,R_E + 0.474\,R_F = 0 \quad (32c)\end{aligned}$$

By the law of symmetry $R_B = R_F$ and $R_C = R_E$. Solution of these equations yields (in pounds):

$$\begin{aligned}R_B &= (0.2467)\,(1{,}000) = 247\\R_C &= (0.2983)\,(1{,}000) = 298\\R_D &= (-\,0.6432)\,(1{,}000) = -\,643\end{aligned}$$

Taking these interactions into consideration, the horizontal thrust $H = 1{,}052$ lb. The coefficients of true deflections are $-\,0.015$, 0.000, and $+\,0.040$ for points B, C, and D, respectively.

Due to $H = 1$, the elongation of the tie girder is $\tau_{HH} = \frac{L}{A\,E}$. The horizontal movement of the arch rib at the springing is $\delta_{HH} = \frac{0.53333\,h^2\,L}{E\,I_C}$, and $\frac{\tau_{HH}}{\delta_{HH}} = \frac{I_C}{0.53333\,A\,h^2} = \frac{48{,}000}{(0.53333)\,(265)\,(1{,}200)^2} = 0.000236$. Therefore, the horizontal thrust that would exist, were the arch rib fixed against the horizontal movement, will be reduced, due to stretch in the girder, only 0.0236 of 1%.

For various positions of the 1,000-lb load, the reduction in horizontal thrust, H_r, due to the elongation of the tie girder, is as follows:

k	H_r (lb)
0.5	$1{,}055 \times 0.000236 = 0.249$
0.3	$857 \times 0.000236 = 0.202$
0.1	$331 \times 0.000236 = 0.078$

Taking the effect of this reduction into account, and with the aid of Fig. 10, Eqs. 32 will be changed to:

$$0.6627\,R_B + 0.7551\,R_C + 0.2621\,R_D - 0.220 = 0 \quad\ldots\ldots(33a)$$
$$0.7551\,R_B + 2.2084\,R_C + 1.2471\,R_D - 0.043 = 0 \quad\ldots\ldots(33b)$$

and

$$0.5242\,R_B + 2.4942\,R_C + 2.1169\,R_D + 0.4882 = 0 \quad\ldots\ldots(33c)$$

The solution of these equations yields practically the same values of interactions as have been found previously in this discussion. Hanger elongations similarly had been incorporated in deflection equations, and the effect of these deformations has been found to be even smaller than the effect of the tie girder stretch.

So far, the girder has been assumed to be perfectly straight, but actually it follows the vertical curve of the roadway. The deformations due to this initial parabolic curvature may be taken into account as follows: Due to $H = 1$, the moment in the tie girder is equal to

$$y' - \Delta = \frac{4\,r}{L}\left(x - \frac{x^2}{L}\right) - \Delta \quad\ldots\ldots(34)$$

and the differential equation of deflection is

$$\frac{d^2\Delta}{dx^2} = \frac{4\,r}{E\,I_G\,L}\left(x - \frac{x^2}{L}\right) \quad\ldots\ldots(35)$$

Therefore,

$$\Delta = \frac{r\,L^2}{3\,E\,I_G}\,(-\,k + 2\,k^2 - k^4) = \frac{L^3}{E\,I_C}\,C'' \quad\ldots\ldots(36)$$

in which r = maximum vertical ordinate of the tie girder = 6.8 ft; Δ = final deflection of the girder, which, being obviously insignificant, has been omitted from the right side of Eq. 35; and C'' = the numerical coefficient of deflection, expressed by

$$C'' = \frac{r\,(-\,k + 2\,k^3 - k^4)}{(3\,L)\,(13)} \quad\ldots\ldots(37)$$

These equations are written with the origin at the springing. Coefficients C'' are recorded in Fig. 12. By means of these coefficients and Fig. 10, the effect of the tie girder deflections due to a horizontal thrust is easily incorporated into the analysis, and Eqs. 33 are changed to:

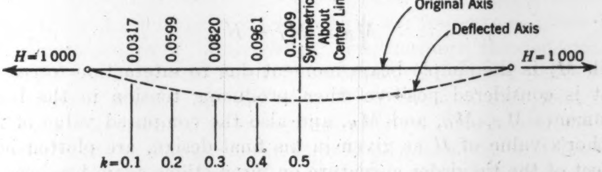

FIG. 12.—COEFFICIENTS OF VERTICAL DEFLECTIONS, C_1, DUE TO $H = 1{,}000$ (Note: $C_1 = 1{,}000\ C''$)

$$0.6417\,R_B + 0.7007\,R_C + 0.2287\,R_D - 0.220 = 0 \quad\ldots\ldots(38a)$$
$$0.7007\,R_B + 2.0678\,R_C + 1.1606\,R_D - 0.043 = 0 \quad\ldots\ldots(38b)$$

and

$$0.4574\, R_B + 2.3212\, R_C + 2.0105\, R_D + 0.4882 = 0 \ldots\ldots (38c)$$

The solution of Eqs. 38 indicates no material changes in the magnitude of interactions that have been determined previously.

Two other factors—interaction moment at the springing and rib shortening—similarly could be taken into consideration in the analysis. (The writer leaves it to students of arch design to prove that the interaction moment at the springing has an insignificant influence on design of this tied arch.) As it stands, the arch rib is considered as being pin-connected to the tie girder. The rib shortening, if taken into consideration, will reduce the value of the horizontal thrust. This in turn would increase the discrepancy between the writer's and the author's H-values.

Similarly, a new set of deflection equations has been made for interactions at every tenth point of the span. The summary of results from this study, for a unit vertical load of 1,000 applied to the girder at $k = 0.5$, is recorded in Table 4.

TABLE 4.—SUMMARY OF INTERACTION FORCES, MOMENT RATIOS, AND COEFFICIENTS OF DEFLECTION

(Horizontal Thrust = 1,054 Lb)

Description	$k = 0.1$	$k = 0.2$	$k = 0.3$	$k = 0.4$	$k = 0.5$
Hanger tension	162	142	148	140	224
M_R/M_T	−1%	+25%	−22%	+10%	+9%
M_G/M_T	+101%	+75%	+122%	+90%	+91%
Final deflection coefficients	−0.0161	−0.0177	−0.0025	+0.0214	+0.0360

The total moment

$$M_T = M' - H\,(y - y') \ldots\ldots (39)$$

is distributed to the girder and arch rib thus:

$$M_G = M' - M_I + H\,y' \ldots\ldots (40a)$$

and

$$M_R = M_I - H\,y \ldots\ldots (40b)$$

in which M_I is the simple beam moment due to interaction forces only; the moment is considered positive when producing tension in the lower fiber. The moments M_T, M_G, and M_R, and also the computed value of M_T using the author's value of H as given in his final design, are plotted in Fig. 13. The effect of the tie girder curvature on interactions again has been found to be quite negligible, varying from -2% to $+1.5\%$.

This concludes a study of the various factors entering into the analysis of the St. Georges tied arch span. After this step the analysis is shifted to an examination of the author's values. It has been found that, assuming the author's influence lines for H as being correct and using the distribution of bending moment, $M_T = M' - H\,(y - y')$, to rib and girder as 7% and 93%, respectively, the resulting values of interactions would not be very different from the values shown in Table 4. Treating these interactions as loads on the isolated arch rib, and allowing neither elongation in the tie girder nor rib shortening, the value of the horizontal thrust becomes $H = 1{,}047$ lb.

Finally, all fourteen interactions for a unit load of 1,000 lb at point 7 were similarly determined by means of Eq. 18, using the given values of $H = 1{,}130$ lb. These interactions, treated as externally applied loads on the isolated arch rib, produce the horizontal thrust $H = 1{,}049$ lb only. Unless the assumption of the elastic properties of the structure was grossly in error, the writer does not believe that the value of the horizontal thrust for the load at point 7 could be greater than 1,049 lb. This limiting value of H is for the case of an arch rib receiving no support from the tie girder. Using the author's value of the horizontal thrust ($H = 1{,}130$ lb), and the resulting values of the interactions, the deflection curve of the arch rib was found to be quite different from the deflection curve of the tie girder. Furthermore, the deflection of the crown point of the arch was found to be negative (upward deflection with respect to original position of the rib). To move the unit load upward, however, the work must be done against gravity. Therefore, some other external force must be acting on the structure besides the unit load. This external force is the discrepancy between the writer's and the author's values of the horizontal thrust. With the value of $H = 1{,}130$ lb, the ends of the arch rib at the springing actually move inward with respect to their original position, which is contrary to the physical behavior of the structure.

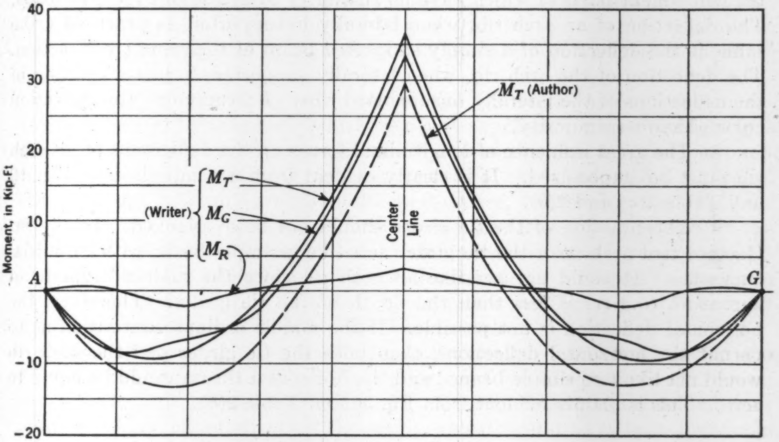

FIG. 13.—MOMENTS M_T, M_R, AND M_G

No analysis was made by means of the coefficients of arch deflections for the other positions of the load. It is possible that the actual properties of the structure, complete data for which are not included in the paper, might influence somewhat the results of this analysis. The writer hopes that, in his concluding discussion, the author will give the missing information, as well as the magnitude of his interactions and deflections.

Conclusion.—This discussion may be summarized under four items, as follows:

(1) In the design of the St. Georges tied arch span the author has compared the deflections of the tie girder, Table 2(*c*), with the deflections of the laterally unsupported arch rib, Table 2(*a*). From the foregoing discussion it is evident that the arch rib is practically fixed laterally, and the design should be based on the comparison of deflections of Tables 2(*a*) and 2(*b*). Therefore, the derivation of the author's formulas beyond Eq. 3 is not justified.

(2) The flitched-beam idea is not applicable for analysis of these structures, the component parts of which have no similarity to deflections for unit loads. The deflection of an arch rib, when laterally unsupported, is practically the same as the deflection of a simply supported beam of the same cross section. The deflection of the arch rib, when laterally supported, is just a fraction of the deflections of the laterally unsupported ribs. Furthermore, the deflection curves have no similarity.

(3) The great influence of longitudinal forces on the deflections of an arch rib must be emphasized. It is clearly evident from a comparison of Fig. 10 and Table 2(*a*) and 2(*b*).

(4) The function of the tie girder should not be overlooked. In the St. Georges tied arch span the tie girder acts like a simple beam with an initial curvature. It could not act like an arch rib since the middle ordinate of curvature (6.8 ft) is less than the depth of the tie girder. Therefore, the horizontal deflection is not possible. If the middle ordinate were such as to permit the horizontal deflections, then both the tie girder and the arch rib would act like two simple beams, and the horizontal thrust would be equal to zero. This is plainly evident from Eq. 30 and Table 2(*a*).

CARLOS A. BEJARANO,[9] JUN. AM. SOC. C. E.—The derivation of the method of analysis of a novel type of arch has been derived most interestingly and soundly by Professor Garrelts.

In arriving at a simplified expression for the distribution of moments between the arch rib and tie girder, the last three terms of Eq. 12 have been omitted, assuming that the error produced thereby is insignificant. The amount of error introduced by this step can be approximated by assuming reasonable limits to the respective factors, but the exact difference may be calculated after the stress analysis has been completed, using the actual computed values for each factor. This condition may be investigated at panel point 4, where the effect is probably the greatest, since it is close to the quarter point of the span where the stresses approach a maximum.

The radius of curvature of the span may be determined by considering the arch rib in the form of a parabola. The vertical deflections may be computed from the moment influence coefficients, applying the principle of virtual work.

---

[9] Parsons, Klapp, Brinckerhoff & Douglas, New York, N. Y.

Using the computed values for both the deflection and radius of curvature, the last three terms of Eq. 12 will then assume the following values: $-\cos\alpha\,\frac{v}{\rho^2} = -0.00000173$; $\frac{v}{\rho^2}\,\frac{d\rho}{dl^2}\sin\alpha = 0.00000179$; and $-2\,\frac{dv}{dl}\,\frac{1}{\rho}\sin\alpha = -0.00000185$. It may be observed that each of these three terms is of the same magnitude, but inasmuch as one of them is of opposite sign, practically the total error will result from either of the other terms. The algebraic sum of the three terms gives -0.00000179.

In order to obtain the precision of the computation, the term $\cos\alpha\,\frac{d^2v}{dl^2}$ may be taken equal to $\frac{d^2\eta}{dl^2}$, which in turn is equivalent to $\pm\,\frac{M}{E\,I_R}$. For maximum positive moment the error is -3.1%, and for maximum negative moment, -3.4%. Since this is probably the largest error involved in Eq. 13, and also since it is of negative sign, the simplified procedure of analysis is therefore justified.

The question may arise as to whether this will be the amount of error involved wherever this method of analysis may be applied. The foregoing values apply specifically to the St. Georges tied arch, but they are a fairly good indication for any other similar structure since none of the factors in Eq. 12, except the curvature, will vary greatly in different arches. Assuming, then, that the third and fourth terms cancel each other and that the total error lies in the omission of the last, one may observe that its magnitude is inversely proportional to the radius of curvature. Thus, the precision is governed by the shape of the arch, and it can be quite accurately determined for any other arch by comparing its curvature with the St. Georges arch.

Under the heading "The Final Design," Professor Garrelts has noted the influence values for H, in which he has included the effects of rib shortening and tie extension, as indicated in Eq. 17. Actually these latter considerations produce a very minor effect on the result, and it would have been justifiable to omit them from the computations, simplifying the work to some extent. The following is a comparison of the values of H with and without the effects of direct stress:

Load at panel point	Values of H With	Without
1	0.2358	0.2380
2	0.4595	0.4639
3	0.6625	0.6687
4	0.8372	0.8452
5	0.9772	0.9865
6	1.0772	1.0874
7	1.1300	1.1408

Professor Garrelts has suggested an alternate method of analyzing the arch by using a transformed section for the rib, instead of for the tie, which would resist all the bending moment and compression while the tie would act only as a tension member. This would be more in conformance with the regular procedure in the design of an ordinary tied arch, and for this particular reason it probably would be preferable to the original scheme. The transformed moment of inertia for the rib would be $I'_{tr} = I_R + I_G \sec \alpha$. When the total bending was transferred to the tie girder, it was resisted by a transformed section whose moment of inertia was $I_{tr} = I_G + I_R \cos \alpha$. The geometric relation that exists between the two transformed sections is quite apparent. Therefore the preliminary analysis yielding the redundant reactions would be similar in each case. However, in the analysis of the loading conditions to produce maximum fiber stresses at any given point, the two methods will not necessarily yield the same results. The maximum fiber stress is the combined effect of the thrust, moment, and shear due to any given loading. Thus, for maximum total fiber stress, the moment must be taken about the kern points of each section, rather than through the apparent neutral axis. The additional moment ($\pm \Delta M$) is a function of the properties of the section in question and may be applied as a correction to the moment influence coefficients in determining the loading conditions for maximum stress at any particular point.

If the moment of inertia of the rib differs from that of the tie, the value of ΔM for the larger section obviously will be greater than for the smaller section. The effect of this difference may be noticeable at those panel points where a reversal of stress has taken place; that is, where the bending moment has changed from positive to negative (or vice versa) under a given loading. This may be observed from the moment influence coefficients shown in Fig. 5. For example, notice the effects in the determination of the maximum positive stress at panel point 1. The moment influence coefficients for point 1 when the unit load is at 6 and at 7 are, respectively, + 0.49 and − 2.69. The additional moment at 7 on considering the kern point of the arch rib is 1.00 and, when the kern point of the tie girder is considered, ΔM is equal to 3.11, which is sufficient to produce a positive moment at point 1. In the latter case, then, an additional panel would be loaded to produce maximum positive fiber stress at point 1.

The number of times that this condition might occur depends on the particular characteristics of the structure. It may be noticed that the difference in each case will involve either the loading or unloading of one panel—that is, a small fraction of the live load, which will not produce a very large discrepancy.

To reduce the errors to a minimum, it would be advisable to make an analysis of that transformed structure which more nearly approximates the true behavior of the bridge.

A. A. EREMIN,[10] ASSOC. M. AM. SOC. C. E.—Analysis of stresses in the arch rib tied with a stiffening girder is an extremely complicated problem. In the technical literature very little can be found on this subject. In computing the stresses in the St. Georges arch bridge, Professor Garrelts has adopted various assumptions to simplify the computations. The writer proposes to clarify, further, the limitations of assumptions adopted in the light of economic aspects of tied arch bridges with stiffening girders.

---

[10] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

From Fig. 6 it is evident that the stiffening girder in the St. Georges bridge is connected to the arch rib by a rigid joint, whereas, in the development of Eq. 3 for the computation of stresses in the arch rib, the author assumed that the stiffening girder is connected to the arch rib by a frictionless hinge. This assumption has a negligible effect on computation of the horizontal thrust in the arch rib, especially for ratios $\frac{h}{L}$ equal to or greater than $\frac{1}{10}$. However, the equations developed with this assumption are not adequate for the design of the arch rib sections at the ends and their connections to the stiffening girder.

The axial stresses in the stiffening girder, produced by the arch rib thrust, are generally small compared with the bending moment stresses. Therefore, sections of stiffening girder are usually varied according to variations of the bending moment stresses along the girder axis. In developing Eq. 17 for the horizontal thrust in the arch rib, Professor Garrelts, however, assumed that the stiffening girder section is constant for the entire length. Evidently with this approximation the refinement of considering that the arch rib section varies directly as cos α (Eqs. 16) has doubtful meaning.

In the design of tied arch rib bridges, an important consideration is the design of the lateral stiffening system. Often economy in material gained by careful computations of the stresses in the arch rib and stiffening girder may easily be lost in the wasteful approximate design of the lateral stiffening system. It is to be hoped that, in his closing comments, the author will discuss a method of designing the lateral stiffening system and will present some principles to govern the selection of panel lengths.

The author is to be commended for making a valuable contribution to this subject.

A. M. FREUDENTHAL,[11] ASSOC. M. AM. SOC. C. E.—When considering the formulas for the design of the tied arch derived by Professor Garrelts, the question immediately arises as to whether the validity of these formulas is not subject to the same limitations as the formulas of the elementary theory of the suspension bridge, particularly taking into consideration the relatively large span of the structure actually designed. High deformability is a common feature of all structures in which a shallow girder suspended from, or supported by, a flexible member provides the bending resistance for unevenly distributed live load. It is this deformability that renders the methods of the elastic theory of structures ineffective in the design of suspension bridges as well as of arches, particularly those with flexible ribs or of long spans.[12]

In general, designers are quite familiar with the fact that considerable differences are to be expected between the bending moments in the stiffening truss of a suspension bridge, computed by the elastic theory, and the actual moments. They are less familiar with the effects of the deflections upon the bending moments in arches. Therefore, a few quite general remarks regarding the limitations imposed upon the validity of elementary formulas by the flexibility of a structure may not be devoid of interest. In no respect do these comments deprecate the method of design presented by the author which, incidentally, is practically unaffected by considerations of deflections.

[11] Cons. Engr., Tel Aviv, Palestine.

[12] "Deflection Theory for Arches," by A. M. Freudenthal, Publications of the International Assn. of Bridge and Structural Engineering, Zürich, Vol. 3, 1935, p. 100.

In non-tied flexible systems (suspension bridges and arches) the bending moment due to live load can be expressed by

$$M = M'_p - H_p\, y \mp (H_w + H_p)\,\eta \ldots\ldots\ldots\ldots\ldots (41)$$

in which p and w denote statical values due to live load and dead load, respectively, and η denotes the deflection of the cross section of the girder considered. Hence, the moments in the stiffening girder computed by the elastic theory are either reduced (suspension bridges) or increased (arches) by the amount $(H_w + H_p)\,\eta$. Owing to the considerable value of the dead-load thrust H_w for large-span structures, the deviation from the elastic theory may attain a comparatively high proportion of the total bending moment.

It can be easily shown that in self-tied structures the bending moment in the girder (Fig. 14),

$$M = M'_w + M'_p - (H_w + H_p)\,(y \pm \eta) \mp (H_w + H_p)\,\eta = M'_p - H_p\, y \,.\,. (42)$$

is not affected by deflection if the flexible member (the arch rib or the cable) has no bending resistance. However, if the bending resistance cannot be neglected (as in most arches), the effect of the deflections upon the value of the bending moments makes itself felt in the rib moments. The real values of

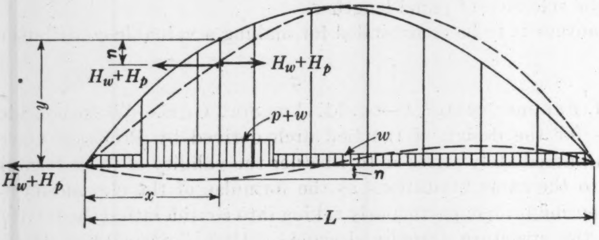

FIG. 14

these moments, therefore, may exceed, considerably, those obtained by simple distribution of the total bending moments between rib and girder according to the respective moments of inertia, as proposed by Professor Garrelts. It is particularly the buckling resistance of the rib that may be impaired by a bending moment exceeding the design value.

C. H. GRONQUIST,[13] ASSOC. M. AM. SOC. C. E.—Preliminary design of the St. Georges tied arch span was made by assuming the 3-ft arch rib as entirely flexible, leaving the 9-ft tie girder to resist the live-load bending moments without assistance from the rib. Under this assumption the action of the structure is exactly analogous to that of the self-anchored suspension bridge, inverted. The flexible arch rib, acting only in direct compression, corresponds to the cable of the self-anchored suspension bridge, whereas the tie girder, acting both in direct tension and in bending, corresponds to the stiffening girder of the self-anchored suspension bridge, which must also transmit the horizontal component of cable stress as a thrust over the entire length of the bridge.

---

[13] Associate Engr., Robinson & Steinman, Cons. Engrs., New York, N. Y.

The action of the two structures being analogous, the equations and method of analysis of the self-anchored suspension bridge can be applied with only slight modification to the analysis of the tied arch with a flexible rib. One point of difference in the action of the two structures is to be found in the effect of vertical curve of roadway and tie girder or stiffening girder. The vertical curve of the stiffening girder will decrease stresses in the self-anchored suspension bridge, but the stresses in the tied arch are increased by the vertical curve. Since both structures are of the "closed" type, resembling simple trusses to that extent, the change in dimensions produced by deflection has no important effect on the stresses determined by the elastic theory using the dead-load dimensions, in the case of either the self-anchored suspension bridge or the tied arch. This is in distinction to the effect of deflection on both the externally anchored suspension bridge and the arch bridge.

A more complex but similar structure consisting of a 3-span continuous girder with the center span reinforced by a flexible arch rib tied to the girder is analogous to the self-anchored suspension bridge with unloaded side spans, except that in the case of the tied arch bridge the side-span girders will not act in direct stress. Again, however, the analysis of the two structures could be made by application of the same methods and equations.

Professor Garrelts gives no derivation for Eq. 17 for the final analysis of the St. Georges tied arch span. Although this may have been assumed to be obvious, the value of this excellent paper may perhaps be increased by clarifying somewhat the theoretical basis for the final analysis. Hanger elongation under live load was considered negligible, as were the tangential components of deflection. Consequently, the angle between the rib and girder at the end of the rib, as well as elsewhere, is not changed during deflection of the structure, and, therefore, there can be no appreciable moment in the rib at its end connections with the girder. The span can be made determinate by cutting the rib at the girder connections so as to eliminate H, the horizontal component of direct stress in the rib and girder. The structure then will consist of two simple beams, the arched rib, and the girder, which are connected by the inextensible hangers and which must participate in proportion to their effective moments of inertia in carrying the live load.

With only the value of the horizontal component of direct stress to be determined, the structure is singly indeterminate, as for the preliminary design. The moment in the structure for a unit value of this redundant is $m = y - y'$, this moment also being divided between the rib and the girder in proportion to their effective moments of inertia. The direct stress in the rib for a unit value of H is $u = \sec \alpha$, assuming the hanger loads to be equal throughout, and the direct stress in the girder is of course $u = 1$. Eq. 17

for H then follows from the substitution of the foregoing moments and direct stresses in the conventional Eq. 2 for a single redundant.

Final analysis of the previously mentioned tied-arch continuous girder can be made by this same method. By taking the basic determinate system as the combination of the continuous girder and the center span simple arched beam, there would remain only the value of H, the horizontal component of direct stress, to be determined by Eq. 17. The actual values of M' in this equation, however, could be taken for the simple span condition, and therefore only for the center span. Similarly, the first term in the denominator could be written $\frac{\Sigma\, m\, m_0\, \Delta l}{I_{tr}}$ in which m represents the moment due to a unit value of H in the basic continuous structure, and m_0 represents the moment due to $H = 1$ in the center span as a simple structure. This follows from the fact that in computing the deflection of an indeterminate structure by the method of the dummy unit load, the value of either M', the moment for the basic determinate condition, or m, the moment produced by the unit load, may be taken for a statically determinate condition. In applying Eq. 18 to obtain the final moments, M', of course, would be taken for the basic continuous system.

HAROLD E. LANGLEY,[14] ESQ.—The tied arch design adopted for the St. Georges bridge is certainly an unusual type in the United States. There seems no doubt that, prior to World War II, there has been a definite trend in design toward the selection of structures which meet esthetic as well as utilitarian requirements. A pleasing design is usually the product of the successful solution of perplexing engineering problems. Professor Garrelts' paper, therefore, is an important contribution to the engineering profession.

Formulas based on the elastic theory seem to have been accurate enough for the design of this bridge, as the results agree with those secured by a model analysis. Inasmuch as both the girder and arch rib are relatively slender members, considerable deformation under load is likely to occur. Because of this tendency, the writer feels that formulas based on the deflection theory would prove more satisfactory, especially if the means of checking the results by a model analysis is not available. In the case of suspension bridges, a design based on the elastic theory requires more material than one based on the deflection theory. The deflection theory does not permit the use of influence lines and, therefore, is somewhat more laborious to apply. Because of the unusual proportions of the bridge under discussion, the writer feels that, if he were called upon to design a similar structure, he would apply the deflection theory.

Although no reference was made to secondary stresses in Professor Garrelts' paper, they were undoubtedly considered in the design. Relatively small bending moments in the arch ribs, in combination with the axial loads, may produce buckling stresses which approach serious proportions. The writer found this to be true in the design of a two-hinged arch, as well as a tied steel arch, each of which had a 425-ft span. As the tied arch had ribs and ties of more conventional proportions than those of the St. Georges bridge, the buckling effect in the latter design might be of major importance. This appears to be very probable, as Fig. 6 indicates that the girder ties and the arch ribs are rigidly connected. If this is so, considerable bending must be transmitted to the ribs from the ties, due, at least, to live load.

---

[14] Engr. of Design, Highway Dept., State of New Hampshire, Concord, N. H.

These comments are not intended in any way as a criticism of a very excellent paper, but should be regarded as a brief résumé of some design features that are likely to be slighted but which are of sufficient importance to merit a thorough investigation. Professor Garrelts is to be commended for bringing the attention of the profession to an unusual but pleasing type of bridge and an interesting solution of its design.

J. M. **Garrelts**,[15] **Assoc. M. Am. Soc. C. E.**—The relative economy of the tied arch form for this structure, compared with other possible types, is discussed by Professor Abbett. Professor Abbett made several economic studies of this kind in connection with this project and thus writes from experience. His discussion also emphasizes the attention given to the problem of appearance in the St. Georges design.

Mr. Karol has shown the close approximation of the value of H used in the preliminary design to the value resulting from the final computations. The difference is almost entirely accounted for by the effect of rib shortening and the extension of the tie girder. The values of H, obtained by a formula similar to Eq. 17 but with the last two terms of the denominator eliminated, or

$$H = \frac{\sum \frac{M^1 \, m \, \Delta l}{I_{tr}}}{\sum \frac{M^2 \, \Delta l}{I_{tr}}} \qquad (43)$$

are as follows:

Load at point:	Values of H
1	0.240
2	0.467
3	0.671
4	0.847
5	0.986
6	1.084
7	1.136

The procedure, suggested by Mr. Karol, for proportioning the total moment between the arch rib and girder will be an aid in calculating the approximate stresses and in determining approximate sections that can be used as the basis for the final analysis.

Mr. Dodge first questions the procedure of neglecting the bending resistance of the arch rib in the preliminary design, although he offers no suggestion as to how the first or preliminary stresses can be computed. In designing any statically indeterminate structure, the designer either can make a guess as to the sections, can obtain them by comparison with a similar structure, or can apply an approximate stress analysis from which trial sections can be obtained. Then, a more accurate analysis is made and the sections are revised as necessary. This latter procedure was used in the design of the St. Georges bridge. The bending resistance of the arch rib later was included in the analysis, as explained in connection with Eqs. 10 to 17.

---

[15] Associate Prof., Civ. Eng., Columbia Univ., and Designing Engr., Waddell & Hardesty, New York, N. Y.

The objection of Mr. Dodge to the use of Eq. 10*a* may be likened to the objection which is sometimes raised against using $\frac{d^2y}{dx^2} = \pm \frac{M}{E\,I}$ for an originally straight beam, when the correct equation is

$$\frac{\dfrac{d^2y}{dx^2}}{\left[1 + \left(\dfrac{dy}{dx}\right)^2\right]^{3/2}} = \pm \frac{M}{E\,I} \qquad (44)$$

Using the reference cited by Mr. Dodge, values are found,[16] which result in Eq. 10*a*.

Mr. Dodge states that "A small initial curvature makes a great change in the effect of longitudinal forces on the deflection of the arch rib." The fact is that the change in curvature is essentially a function of the bending moment.

On the assumption of a parabolic rib and only five hangers, Mr. Dodge attempts to compute the forces in the structure. In the St. Georges bridge there are fourteen hangers and the rib is polygonal, being straight between hanger connections, as shown in Fig. 6. He contends that the writer's values for *H* are too high. The following values were determined from the model analysis made at Princeton University at Princeton, N. J., under the direction of Prof. E. K. Timby, Assoc. M. Am. Soc. C. E.—

Load at point:	Measurement of *H* at a point in member:	
	$L_7\,L'_7$	$U_7\,U'_7$
1	0.226	....
2	0.450	....
3	0.662	0.661
4	0.820	0.838
5	0.971	0.971
6	1.081	1.081
7	1.135	1.132

These values, which are in agreement with the theoretical values used, are probably more nearly correct than those computed by Mr. Dodge, using the assumptions he has made; and the increase in the moment M_T in Fig. 13 does not actually exist, if the writer's values of *H* are accepted as correct.

To summarize: Mr. Dodge's conclusions (1) and (2) are the result of a misconception of the writer's procedure in applying the theory used in the paper. Furthermore, his conclusions (3) and (4) appear to be based on a mistaken conception of the writer's development. His statement that "The great influence of longitudinal forces on the deflections of an arch rib must be emphasized" means nothing more than that the correct bending moment must be taken into account. If the deformations due to direct stresses are neglected, the deflection of an arch rib is almost entirely due to bending moment, and the analysis used by the writer certainly gives full attention to the moment. Study of the writer's development will show that there is no assumption that involves a horizontal displacement of the ends of the arch rib with respect to the tie girder.

---

[16] "Strength of Materials," by S. Timoshenko, D. Van Nostrand, 1930, Pt. II, pp. 468–469.

Mr. Bejarano has kindly evaluated certain terms of Eq. 12 which the writer neglected in later formulas. From his result, the procedure seems to be justified. Although the effects of rib shortening and tie extension are small, they should probably be considered because a small change in H affects the moment by an amount equal to the change in H times y-y'.

The procedure of calculating the structure by transforming the tie to produce a rib with a transformed moment of inertia I'_{tr} also has been discussed by Mr. Bejarano. He shows that the general results by the two analyses would be almost the same but that in the details there are certain differences which indicate an advantage in assuming that action which is more nearly in accord with the structural behavior.

According to Mr. Eremin, the procedures used by the writer are not adequate for the design of the end connections of the arch rib to the girder. In the first place, the hanger $U_1 L_1$ has practically no change in length so that in triangle $U_1 L_1 L_0$ angle $U_1 L_0 L_1$ is changed only by the moment at U_1 and the moment at L_1. Since these two moments will have the same sense, that is, positive or negative, and both will be small, any resulting moment at L_0 also will be quite small.

The writer does not agree with Mr. Eremin's statement regarding the assumption of constant stiffening girder section in Eq. 17. Actually the summation in the equation indicates that the girder is considered made up of segments over each of which the section is constant. Actually fifteen sections, each one panel in length, were used in the analysis.

The design of the lateral system was made in a manner similar to that used for the lateral system of a curved-chord through-truss bridge. In the arch-rib lateral system, the arch rib forms the chords, and the laterals and struts, the web system, with a portal extending from U_2 to L_0. The top laterals and struts are determined in most cases on the basis of minimum $\frac{l}{r}$ rather than by stress.

The writer is grateful to Mr. Freudenthal for his discussion of the general deflection theory of arches and suspension bridges; also for calling attention to the effects of deflection on self-tied structures.

During the design of the St. Georges tied arch span, it was often spoken of as an inverted, self-anchored suspension bridge. Mr. Gronquist has pointed out this analogy. He has also called attention to the action of these two self-tied structures as contrasted with those externally anchored. In addition, Mr. Gronquist has discussed the use of the tied arch with a continuous girder and has outlined the procedure to be used in solving this type of structure.

The writer considered the development of Eq. 17 to be the same as that for Eq. 4, and therefore did not repeat it. The only difference in the two cases is that, in Eq. 17, the tie girder is considered as a transformed section which includes the bending resistance of the arch rib. Actually, in the assumed singly indeterminate structure, the statically determinate substitute structure can be selected in several different ways.

Mr. Langley's statement regarding formulas based on the deflection theory already seems to have been answered by Mr. Freudenthal and Mr. Gronquist. In this self-tied structure, the deflection theory agrees with the analysis given because the arch rib and tie girder deflect the same amount.

The buckling resistance of the arch rib was considered and was found to be ample; and, although the hangers are connected to the arch rib by rigid connections, the bending moment transmitted by the hangers is very small because the hangers are quite flexible.

In conclusion, the writer wishes to express his thanks to those who have discussed this paper.

RELATIVE ANGULAR, LINEAR, AND TRAVERSE ACCURACIES IN CITY SURVEYS

By S. A. Bauer,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. Cleveland B. Coe, W. H. Rayner, Philip Kissam, George D. Whitmore, C. C. Miner and W. O. Byrd, G. Brooks Earnest, and S. A. Bauer.

Synopsis

The methods, procedures, and accuracies of the private practicing surveyor in the past were determined by the algebraic sum of a number of purely local and personal conditions. Each individual locality had its own standards and each surveyor within the locality was an authority unto himself.

Standardization of title search and mortgaging practices throughout the United States now combines with an awakened professional consciousness among the surveyors to demand a standardization of procedure, accuracy, and practice. Much is being accomplished on the standards of practice, but on the question of accuracy (compatible with the peculiarities of the profession) there is little information.

Existing investigations into survey accuracy fall generally into (1) studies of surveys of high precision for specialized purposes, and (2) studies of purely instrumental accuracies under carefully controlled conditions. Although both are interesting, neither indicates accuracies the surveyor can depend on under the conditions and with the equipment that the economics of the profession force upon him.

This investigation was made in that direction. The study is made of actual work that was performed over a period of fifteen years, for clients, in the regular private practice of surveying. The methods and equipment that have been used by the writer for that period are indicated merely for record and are not held out as necessarily good or advisable.

Accuracies as obtained in active practice (angular, linear, and traverse) are tabulated. The factors contributing to accuracy are investigated and certain conclusions that seem to be indicated by the facts, relative to methods and

---

Note.—Published in May, 1942, *Proceedings*.

[1] (Bauer Surveys Co.), Cleveland, Ohio.

equipment, are advanced. It is the hope of the writer that similar studies will be made in other localities with other methods and equipment so that a true standard of obtainable accuracy can be determined for the practicing surveyor.

INTRODUCTION

The purpose of the study was to determine the accuracies that were obtained in survey practice by the office of the writer, a surveyor in the metropolitan area of Cleveland, Ohio, with the ordinary equipment of the profession, under conditions imposed by business necessity, traffic and weather, and economic considerations. The equipment used was: 1-min transits of standard American manufacture; 100-ft steel tapes (graduated throughout into feet, tenths, and hundredths), ¼ in. wide and 0.015 in. thick; plumb bobs; hand levels; thermometers graduated to 2° F; sighting rods (6-ft and 8-ft lengths of ½-in. round solid steel); and spring balances graduated in half-pound intervals from 0 to 30 lb.

OBSERVATION METHODS

Angular observations were made in the usual manner. The instrument was set carefully over the point by plumb bob, and stations being observed were marked by sighting rods, which were generally plumbed by balancing in the hands of the rodman and checked by instrument. If the day was windy, or if only a small part of the rod was visible to the instrumentman, the rodman plumbed his rod by plumb bob. When a rod was "planted" instead of being held during the observation, the "planting" was done by instrument.

The angle was generally observed in a clockwise direction, sighting from the center of one rod to the center of the other. All angles were turned six times for a set. The first and sixth turns were read and recorded to the nearest 30″ by estimation. The final reading was divided by six for the value of the set and angle. Only one vernier was read for economy of time. If the mean of six turns was more than 30″ removed from the first reading, the angle was re-observed. In most cases, all six turns were made with the telescope in one position. Where a re-observation was made, the telescope was inverted. (Subsequently this procedure was changed to three turns with telescope direct and three reversed.)

In taping, the tape was generally held suspended throughout. The difference in level between tape ends was observed by hand level and added to the amount necessary to clear obstructions. Points were transferred to the ground by plumb bob.

Tape lengths were marked by arrows drawn with lumber crayon when the taping was over pavement or sidewalk. In other cases the ground was leveled with the foot and a small headed nail was used to mark the point.

Only in recent years has a spring balance been used. About 80% of the measurements under study herein were made without the use of a spring balance. In those cases the tension was estimated with a tendency toward over-pull in order to compensate for taping errors which in general have the effect of a short tape. The tape was lined in by eye by the rear tapeman, the line ahead being marked by a sighting rod. In all cases, after setting a point for a tape end mark, a check measurement was made before proceeding.

It is not the intent of this paper to advocate the foregoing procedure as being either good or proper. The writer merely catalogs the methods and equipment that produced the data herein studied.

Extent of Tabulations and Working Conditions

Since the purpose of this study was to determine accuracies actually obtained in practice, no lines, angles, or traverses were run particularly for this study. The observations used herein represent all field notes and calculations, of the period from 1925 to 1940, applying to specific jobs that this office was hired to perform.

The work included in this study is almost exclusively confined to metropolitan Cleveland. About 60% of the work is within the areas of city development and about 40% in the outlying country. About 75% of the city work is in flat territory with grades that rarely exceed 4%, and the remaining 25% is in territories where the grades generally vary between 8% and 12%.

The outlying country work, involving about 40% of the work studied herein, is distributed as follows: 40% in flat country with grades up to 5%; 20% in rolling country with grades between 5% and 10%; the remaining 40% in rough country ranging from moderately rough terrain to extremely rough where distances had to be measured by slope measurements and vertical angle.

The lengths of traverse sides and of other measured lines vary from 50 ft to 4,000 ft with a mean length of 700 ft for all lines. Traverses vary in total length from 500 ft to 18,000 ft and from 4 to 37 sides per traverse. The average length of traverse is 4,300 ft.

The work studied herein was performed during all months of the year. All climatic conditions are represented except heavy rain or snow, the temperature ranging from 15° F to 95° F.

Methods Used in This Study

To compare angular and linear accuracies and the effect of these accuracies on traverse closures, a common unit for their measurement was determined; that is, the error was expressed as one part in x thousands. This quantity was obtained in linear observations by dividing the calculated probable error of a single measurement into the length of the line. In traverse closures it was obtained by dividing the error of closure into the length of the traverse.

In angular observations the probable error of each single set of six turns was calculated in terms of seconds of angle. The tangents of the angular errors converted to one part per x thousands were then determined and used as the expression indicating the linear effect of the angular error.

In most of the graphs which accompany this study, the vertical coordinates represent the accuracies in terms of one part in x thousands; the horizontal coordinates represent the percentages of the various accuracies. By a reciprocal method, the accuracies in terms of one part in x thousands can also be expressed as y parts per hundred. This latter expression of accuracy is hereinafter used for purposes of establishing mean values.

The probable error of a single observation is expressed by the formula

$$r_s = 0.6745 \sqrt{\frac{\Sigma v^2}{N - 1}} \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

in which r_s is the probable error of a single observation, v is the residual from the mean, and N is the number of observations. When $N = 2$, Eq. 1 becomes,

$$r_s = 0.9539\, v \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Further, the probable error of the mean of two or more observations is expressed by the following formula:

$$r_m = 0.6745 \sqrt{\frac{\Sigma v^2}{N\,(N - 1)}} \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

which, when $N = 2$, becomes

$$r_m = 0.6745\, v \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

TABULATION OF ANGULAR READINGS

To determine the accuracy of a single reading of a 1-min transit, 176 sets of angles were tabulated. In each case the first reading and the mean of six turns were recorded, together with the difference between the first reading and the mean of six. These results were as follows:

Difference, in seconds, between the first reading and the mean of six (equal to, or less than)	Percentage of total (176) readings
0	15
10	41
20	63
30	83
40	89
50	96
60	98
70	100

The mean difference of the entire 176 angles tabulated was found to be 21″.

Sixty-six angles re-observed from the same instrument setup were then tabulated. The probable error of each single set (the mean of six turns) of each pair of sets was calculated and tabulated and the percentages of the various accuracies determined. The results are plotted as curve 1 in Fig. 1. The mean probable error of the 66 single angles studied in this classification is 3.8″. It is to be noted that all of the angles represented in this classification were re-observed from the same instrument setup, with no appreciable time lapse between observations.

In Fig. 1, the mean value is plotted as a short horizontal line intersecting curve 1 at 3.8″. In order that later in this study the angular and linear accuracies may be compared, curve 1 was then converted into curve 3, shown in Fig. 2, by plotting the tangents (expressed in terms of one part in x thousands) of all angular values of curve 1, thereby giving an angular-error curve in the common unit of one part in x thousands.

After a time lapse ranging from a few days to ten years, 70 angles were then re-observed and studied. Again, the probable error of each single set (the mean of six turns) of each pair of sets was calculated and tabulated and the

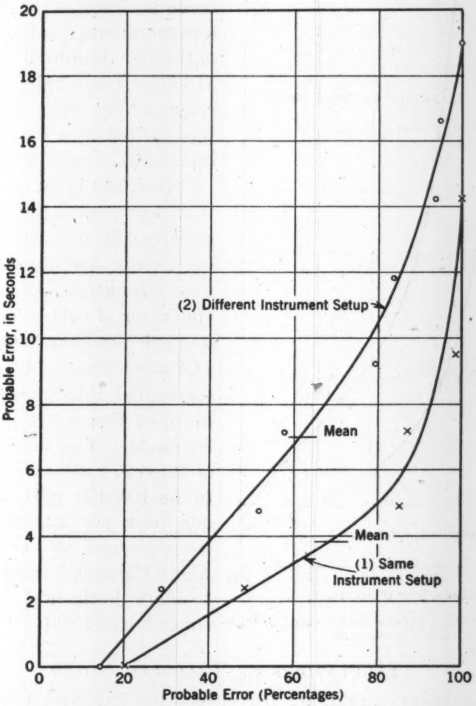

FIG 1.—ANGULAR ACCURACIES IN SECONDS OF ARC; PROBABLE ERRORS OF SINGLE SETS OF SIX TURNS

percentages of the various accuracies determined. The results are plotted as curve 2 in Fig. 1. The mean probable error of the 70 single angles studied in this classification is 7.0″. The mean value was plotted as a short horizontal line intersecting curve 2 at 7.0″ (see Fig. 1).

Again, in order to compare angular and linear accuracies, curve 2, Fig. 1, was converted into curve 4, Fig. 2, by plotting the tangents (expressed in terms of one part per x thousands) of all angular values of curve 2, giving this angular-error curve in the common unit of one part in x thousands.

TABULATIONS OF LINEAR READINGS

For this study 120 lines, retaped by the same party within the same day, were tabulated. The probable error of each single measurement of the pairs of measurements was calculated and converted into the unit of one part per x thousands. The mean of the probable errors and the percentages of the various accuracies were determined. The mean probable error of these 120 line measurements was found to be 0.00319 parts per hundred, or one part in 31,300. These values were plotted as curve 5, Fig. 3(a). The mean value was plotted as a short horizontal line intersecting curve 5 at 31,300.

Next, 274 lines, remeasured during the 15-yr period, but with time lapses between the two measurements varying from a few days to twelve years, were tabulated. As before, the probable error of each single measurement was calculated and translated into the unit used herein; the accuracies were segregated into percentages, and the mean of the probable errors was determined. The mean probable error of these 274 measurements was found to be 0.00439 part per hundred, or one part per 22,800. These values were plotted as curve 6, Fig. 3(a). Again the mean value is indicated as a short horizontal line intersecting curve 6 at 22,800.

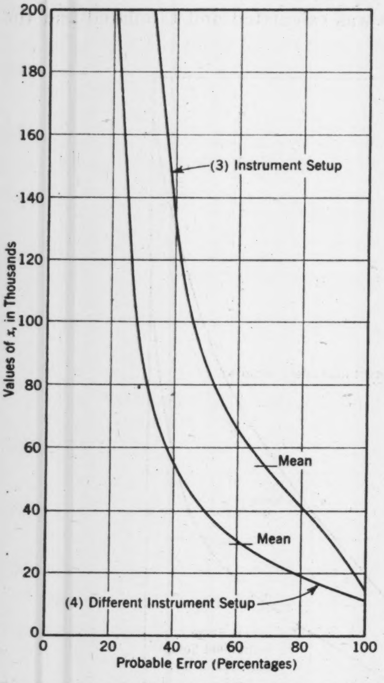

FIG. 2.—ANGULAR ACCURACIES EXPRESSED AS ONE PART IN x THOUSANDS

TABULATIONS OF TRAVERSE NOTES

During the 15-yr period, 92 traverses were run and tabulated by their errors of closure expressed in terms of one part in x thousands. (Due to lack of a precise control in this territory, all traverses herein are closed upon themselves as a complete loop.) The percentage of the various accuracies was determined as in previous investigations of angular and linear accuracies, and the mean of the traverse errors was determined. The mean traverse closure error of the 92 traverses under consideration was found to be 0.00442 part per hundred or one part in 22,600. These values were plotted as curve 8, Fig. 4, the value of the mean error again being indicated by a short horizontal line at 22,600.

FINDINGS OF FACT FROM TABULATIONS

To analyze more clearly the facts determined by this investigation, curves 4 and 6 are plotted in Fig. 4, with curve 8. These are the accuracy curves of angles observed at different times, lines measured at different times, and traverse closures. The mean value of each curve is also indicated in the manner previously described, as well as the levels of first-order, second-order, and third-order accuracies, according to the Society's *Manual of Engineering Practice No. 10* ("Technical Procedure for City Surveys"). Examination of the curves in Fig. 4 and the data from which they were plotted discloses the following facts:

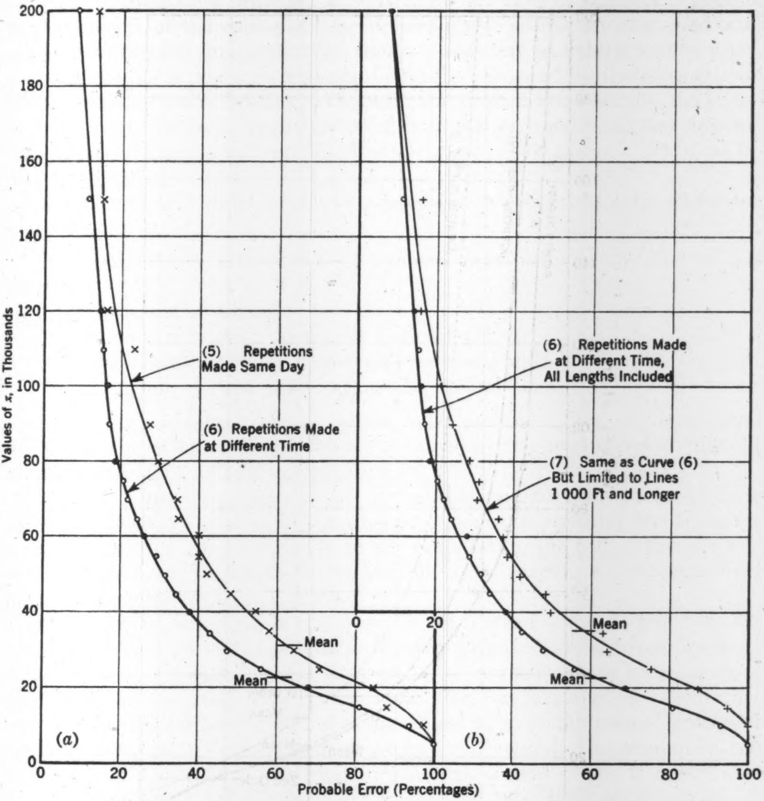

FIG. 3.—LINEAR ACCURACIES, EXPRESSED AS ONE PART IN x THOUSANDS

(*a*) All traverses run in the 15-yr period close with a third-order accuracy or better;

(*b*) 83% of the traverses close with a second-order accuracy or better;

(*c*) 39% of the traverses close with a first-order accuracy or better;

(*d*) The mean of angular accuracy exceeds the mean of linear accuracy by approximately 30%;

(*e*) The curve of traverse closure accuracy is practically identical with the curve of linear accuracy in the normal ranges;

(*f*) The probable error in a single reading of a 1-min transit is ±25″. The mean difference between a single reading of a 1-min transit in a group of six readings, and the mean of that group is ±21″;

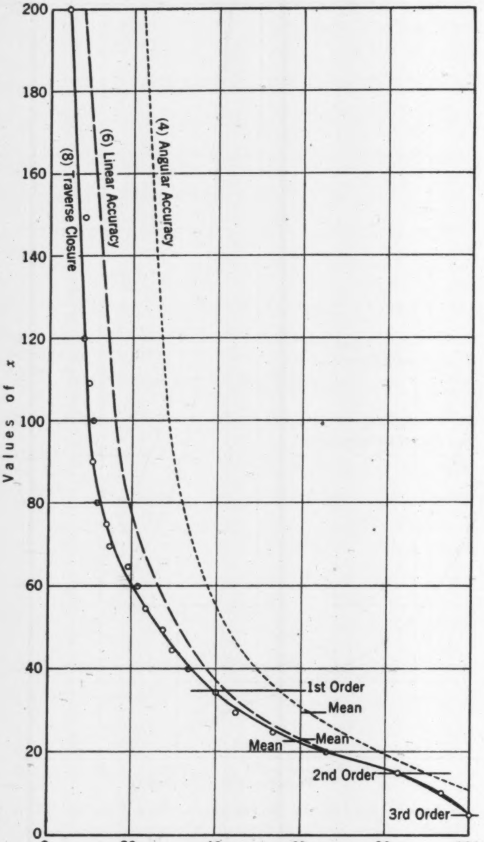

FIG. 4.—TRAVERSE, MEASUREMENT, AND ANGLE ACCURACIES, EXPRESSED AS ONE PART IN x THOUSANDS

(*g*) The mean probable error of an angle re-observed after an appreciable time interval with a 1-min transit turned six times is 7″, or a mean difference of 15″ between the two observations;

(*h*) The mean accuracy of angles re-observed at the same time from the same instrument setup is 84% greater than the mean accuracy of angles re-observed after an appreciable time lapse; and

(*i*) The mean accuracy of lines double taped at the same time is 37%

greater than the mean accuracy of lines remeasured after an appreciable time lapse.

Factors of Accuracy

The foregoing data provide information on the basis of which it is possible to study some of the causes of inaccuracies under actual working conditions with a view toward determining the limits of accuracy and the extent to which accuracy can be increased within the limitations imposed by the economics of the profession, traffic, weather, and local conditions. For example, the variations in the accuracies of angles observed from the same setup can be compared with those of angles observed at different times—a difference of 84%, as indicated previously.

The factors that differ in the two categories which might account for the variation are:

(1) Variations in instrument adjustment, principally in the line of collimation;
(2) Movement of points;
(3) Errors in centering the transit over the point;
(4) Errors in the marking of observed stations; and
(5) Refraction of light due to atmospheric conditions.

It is to be noted that, except for the movement of points, all factors tend to indicate the lower accuracy (the one obtained by re-observations of different times) as the more probably correct one.

Item (1), the adjustment of the instrument, would seem to be of little significance in the variation of the accuracies, since in inverting the telescope for the re-observation of angles from the same setup, the collimation error is corrected in much the same degree that it is by varying adjustments over different time intervals.

In Cleveland, monuments are generally of marked stone or iron bars set below grade and protected by cast-iron boxes in paved street areas; or stone monuments or iron bars set at or near grade but not enclosed in boxes in areas other than pavements. This system rates high for permanence. Nevertheless, experience indicates measurable movement in even the best of protected street monuments. To determine the effect and possibly the amount of the movement of points, and the extent to which movement of points contributes to the difference of accuracies under study, the tabulation of accuracies of angles observed at different times was broken down according to the time interval between the two observations:

Time interval (yr)	Mean probable error (sec)
>0.5	7.3
0.5 to 2	6.4
2 to 3	9.2
3 to 4	6.5
4 to 5	6.6
5 to 10	5.3
10 to 15	7.6
Mean error for period	7.0

It seems clear, from the absence of any pattern in the foregoing and from the lack of consistent change with increasing time lapse, that either the movement over a long period becomes a compensating factor, or the error is smaller than the other contributing errors and, therefore, is lost among them. With Items (1) and (2) eliminated as determining factors in the variation of accuracies under discussion, only Items (3), (4), and (5) are left as determining factors.

The minimum difference between the two mean errors is 3.2″. Then three factors—Item (3) error of centering, Item (4) error of rod position, and Item (5) refraction—contribute to an increased mean error of 3.2″. It seems clear, then, that under the conditions of work stated herein there is a basic minimum error of angular observation of 3.2″.

It is to be noted that none of the three contributing factors to this basic minimum error are altered by (*a*) the calibration of the transit plate, or (*b*) the number of times that the angle is repeated at one setup. Therefore, when the basic error of 3.2″ is reached, neither precision of instrument graduation nor number of repetitions affects the actual result. Then, for city survey work that must be performed during all but the most extreme of weather conditions (assuming the use of sighting rods for pointings and plumb bob centerings of instruments), it would seem that the only advantage to a transit calibrated more closely than 1 min would lie in the fact that the limit of accuracy can be reached more quickly—that is, with fewer repetitions.

This leads to the question: How many repetitions are necessary to reach the ultimate accuracy fixed by external conditions, with a 1-min transit, that ultimate being, according to these tabulations, ±3.2″?

Previously herein it has been shown that the mean probable error of a single observation observed twice from the same setup (in each case an observation being the mean of six turns) is 3.8″. The mean probable error of the mean of the two observations from the same setup is then 2.7″, since the error of the mean is $r_m = \frac{r_s}{\sqrt{N}}$. It is to be emphasized that these are not presented as actual accuracies but merely the relationship of accuracies of angles observed by six turns as against angles observed by twelve turns, and all from the same setup.

It has also been shown that there is a 3.2″ minimum fixed error for the conditions and type of work studied herein, which error establishes the ultimate accuracy that can be obtained.

Since, as noted, the calculated probable error of six turns is 3.8″, and that of twelve turns is 2.7″, it should then require approximately nine turns to equal the limit of accuracy obtainable from one setup, with a 1-min transit, under the foregoing conditions and type of work.

In the work described herein, the average length of line and traverse side is 700 ft. The effect of the centering and rod position errors can be reduced by longer sights, but that is apart from the type or accuracy of transit used. An optical device such as is provided on some Swiss instruments, however, should materially reduce the centering error.

In a manner similar to that used in the investigation of the variation of the foregoing angular accuracies, the variation of linear accuracies is now studied. As noted, the calculated accuracies of lines retaped at the same time are 37% greater than the accuracies of lines remeasured after an appreciable time interval.

The factors that might contribute to this variation are: Differences in tape lengths, movement of points, errors in tension on tape, and errors in determining temperature of tape. Again, except for possible movement of points, all factors tend to make the lower accuracy (lines remeasured with a time lapse) the more probably correct one.

On the accuracy of the tapes used, the writer has few authentic data. There should be a marked uniformity in tape lengths due to the type of tape used, but the manufacturer's statement of uniformity and accuracy has been the principal assurance. One dependable test was made, which showed an error of 0.0005 ft at 68° F, and 20-lb pull when suspended from the ends. Frequent tests by ordinary taping methods of new tapes against those which have been in service have never disclosed a variation of more than the thickness of a division mark, which is about 0.002 ft.

After these tapes have been in use for several months, however, they develop an exaggerated stretch for the standard pull when fully suspended, although they will continue to check for length when supported throughout at 10 lb. This is unquestionably due to the fact that the thickness of the tape has diminished through wear. When this error becomes noticeable, the tape is no longer used for anything but minor measuring.

To determine the extent to which the movement of points contributes to the variations under consideration, a breakdown of the measurement tabulation was made on the basis of the elapsed time, as in the study of angular accuracy variations. The results are as follows:

Time interval (yr)	Mean probable error, in parts per hundred
>0.5	0.00467
0.5 to 2	0.00405
2 to 5	0.00334
5 to 10	0.00389
10 to 15	0.00484
Mean error of period	0.00439

Again no pattern or variation is discernible in relation to time. It would seem, then, that the time element beyond an immediate remeasurement has no deciding effect upon the accuracy of remeasurements, and, therefore, the movement of monuments is either a smaller error than the other errors involved, or the movement is compensating over a period of time.

Errors of tension are now being corrected in a large measure by the use of a spring balance. Insufficient data are available to determine the amount of this error prior to the use of the spring balances.

Unquestionably the largest source of taping error, and probably the greatest contributor to the variations of accuracy under discussion, is the difficulty of determining tape temperature on sunny days. During the summer months pavements are often 15° warmer than the air only 4 ft above them. A tape that has been in the sun on a hot day will become too hot to hold. In winter a tape will absorb heat from the direct rays of the sun in spite of low air temperatures.

No thermometer that the writer has used, which will stand daily use, can be depended upon for more than either air or pavement temperature. In general, when there is a wide discrepancy between the two, an attempt is made to estimate the temperature at tape level and tape temperature. Where a measured line passes through an area that varies widely as to sun and shade, some attempt is made to estimate the mean temperature for the line.

As previously indicated, the mean probable error of a single measurement of a pair of measurements made at the same time is 0.00319 part per hundred, and the mean probable error of a single measurement of a pair of measurements made at different times is 0.00439 part per hundred. Furthermore, it follows that the mean probable error of the mean of two measurements made after an appreciable time interval is 0.00310 part per hundred. From this it seems clear that a remeasurement at the same time will in actual fact not increase accuracy (omitting from consideration at this time an actual mistake of reading, marking, etc.), since the probable error of a single measurement is already within 3% of the accuracy of the mean of two measurements made at separate times.

Curve 6, Fig. 3(*b*), represents the accuracies of lines of all lengths that were repeated after an appreciable time lapse. Curve 7, Fig. 3(*b*), was derived from the same tabulation but was limited to lines of 1,000 ft and longer. In each case, the mean value of the probable errors included in the curves is indicated by a short horizontal line intersecting the curve at the level of the mean error. As determined previously, the mean probable error of curve 6 is one part in 22,800. The mean probable error of curve 7 is one part in 35,500. It is apparent from Fig. 3(*b*) that accuracies are approximately 50% greater for lines of 1,000 ft and longer than for lines of all lengths.

Examination of Fig. 4 indicates a marked similarity in linear and traverse accuracies in the normal ranges of precision. As noted, angular accuracies are about 30% higher. The similarity between the traverse accuracies and the lesser of the two contributing accuracies is in accordance with the probabilities. Although it is impossible to predict how linear and angular accuracies will combine within a single traverse (there are sixty-four possible combinations of the errors in a triangular traverse), nevertheless, in a large number of traverses the mean result can be determined.

To illustrate, the linear error of a traverse side and the angular error affecting that side can either be in such a direction that they are added, or in opposite directions and therefore subtracted. In a large number of traverses, the traverse errors are made up of large numbers of linear and angular errors, some of which compensate each other as the difference between the two, and some of which combine to the total of the two. The probability of one is equal to the probability of the other; therefore, the mean of the two extremes will represent the resulting traverse error for a large number of cases.

If the angular error is represented as E_a, the linear error as E_l, and the traverse error as E_t, then the traverse error (E_t) of a single traverse will lie between the two extremes, $E_l + E_a$, and $E_l - E_a$, assuming E_l is numerically greater.

The traverse error of a large number of traverses will be the mean of the two extremes, since the probabilities of each are equal:

$$E_t = \frac{(E_l + E_a) + (E_l - E_a)}{2} = E_l \ldots\ldots\ldots\ldots\ldots (5)$$

—if E_l is the larger of the two contributing errors.

On this basis then, with the same angular accuracy as shown by curve 4, Fig. 4, and traverse sides of 1,000 ft or more as shown by curve 8, the traverse accuracy should increase, making the angular accuracy the determining factor of traverse accuracy.

As a check against this hypothesis, the traverses included in the tabulation for curve 8 were segregated as to the mean length of traverse sides. Twenty of the traverses in the tabulation had a mean length of side of 1,000 ft or more. The mean error of these traverses was found to be 0.00350 part per hundred or one part in 28,600. The mean value of curve 4 is one part in 29,400. The writer's hypothesis—that traverse accuracy is determined by, and equal to, the least accurate of the two contributing factors—is substantiated in this test by within 3%.

It would seem, then, that with the same equipment and methods now in use in the writer's office and described previously herein, a mean traverse closure of one part in about 30,000 can be maintained without undue consideration of climatic conditions, provided that traverse sides could be maintained at 1,000 ft and more.

It is of further interest to note that, for various accuracies, the percentage of the total number of traverses in rough terrain was as follows:

Traverse accuracies	Percentage of total in rough terrain
1 : 9,000 or less	100
1 : 14,000 or less	71
1 : 19,000 or less	55
1 : 20,000 or more	25

The traverses were studied for variations of accuracy based upon the over-all length of the traverse. Nothing conclusive was found, and the variations wavered back and forth about the curve for all lengths.

The dominating factor is length of side rather than length of traverse. The length of side in turn is determined by conditions of terrain. The tabulation does not contain a sufficient number of traverses of the same traverse side lengths to permit a study of the effect of variation of traverse over-all length.

CONCLUSIONS

This study has established certain findings of fact as to accuracies that have been obtained in actual survey practice. A number of these were itemized under the heading "Findings of Fact from Tabulations" (see Items (*a*) to (*i*)). Three other items follow from the discussion presented under the heading "Factors of Accuracy":

(*j*) The mean probable error of remeasurements of the same line with ordinary equipment is 0.00439 part per hundred, or expressed differently, the difference between remeasurements of the same line averages 0.00920 part per hundred;

(*k*) The accuracy of measurement of lines of 1,000 ft and more is greater than that of lines shorter than 1,000 ft; and

(*l*) Accuracies of traverses with sides having a mean length of 1,000 ft or more are greater than those with sides having mean lengths under 1,000 ft, other factors being equal.

All the foregoing items support the following conclusions:

(1) There is a definite limit to the accuracy that can be obtained from a single setup of a transit. This limit is independent of the fineness of the transit's plate calibration, and of the number of repetitions in the observation; and it should be reached, by a good 1-min transit under average working conditions, at nine turns.

(2) Retaping of a line, forward and back, under average conditions, adds nothing to actual accuracy (except to locate mistakes in taping).

(3) In the long run, accuracies of traverses are determined by, and equal to, the lesser accuracy of the two contributing factors of taping and angular observation.

The foregoing findings (Items (*a*) to (*l*)) and reasoned conclusions ((1) to (3)) pose the following questions:

A. Present specifications for survey accuracy stress the error of closure primarily. In areas that lack a precise control, are such specifications adequate to assure a desired accuracy?

B. Is the trend toward transits of ever-smaller plate graduations justified for city work?

C. Might not accuracies of transits for city surveying be maintained at their present level, and work of setup and reading be facilitated by changes in design?

DISCUSSION

Cleveland B. Coe,[2] **M. Am. Soc. C. E.**—The author of this paper joins a small and select group—those who offer something for the advancement of the professional knowledge and ability of the surveyor. In any issue of almost any technical publication, structural, hydraulic, and sanitary engineers may find results of investigation and analysis which will bear more or less upon their daily problems, but the land surveyor is the "forgotten man" of the profession, although not of the general public, to whom he is the "engineer."

Truly, the phrase used by Mr. Bauer is a masterly one (see "Synopsis"): "Under the conditions and with the equipment that the economics of the profession force upon him." The economics of the profession have forced considerable shoddy practice on many men who knew what should be done to give reliable results to their clients. The clients neither know nor care how the surveyor arrives at his results; nor are they interested in the accuracy attained, in many cases.

The writer surveyed farm lands for many years, in competition with day labor of the crudest type. Very frequently he went on a job alone, and assistance was provided by the client, in the form of his sons and nephews. This was, and is, a condition of very common occurrence and will continue as long as registers of deeds are permitted by law to accept the descriptions and plats made by unlicensed surveyors. Much has been done to correct this condition, but much educational work remains before the landowner becomes willing to pay the price which efficient help and accurate measurement of land should reasonably cost.

The paper deals entirely with city surveys and concerns itself with property of considerable value. The writer's experience was with mountain and farm land, worth from $10 to $300 per acre, and the conditions and equipment forced upon him by the economics of the profession were certainly inadequate, even for so low a valuation. If similar studies are presented, as hoped by the author, perhaps someone will present the rural point of view.

The survey of farm lands by the private surveyor, as distinguished from cadastral surveys of large areas by government or corporation surveyors, is generally in one of the following categories:

(1) To establish a dividing line or a disputed corner;
(2) To ascertain true acreage; or
(3) To subdivide property for inheritance or sales purposes, either in large tracts or small lots.

Case (1), in the writer's experience, comes more under the head of an art than a science. In Tennessee, there are no applications of the law of township and section, but all property traces back to original grants, mixed up in the wildest confusion. In no case has the procedure been clear-cut and capable of solution entirely by scientific methods and careful application of angular and linear measurement. Diplomacy is an important tool of the surveyor, and practically all final results are the result of compromise, either known or unknown to the parties to the dispute. Under such conditions, repeating angles and tension in a tape play no part.

---

[2] Lt. Col., Corps of Engrs. U. S. Army, Knoxville, Tenn.

Case (2) requires closer adherence to the rules and is the one in which old notes can be reviewed and rerun. Unfortunately for such studies, it is very seldom that a corner monument can be exactly occupied. Nearly all lines are offset lines, with temporary monuments, tied to the corners by side shots. Here the parsimony of the owner plays a great part, not only by preventing the employment of skilled help but by making it necessary to run the offsets in places requiring the least clearing, not following the boundary as closely as it should be. Here, also, the rural objection to measurement in a horizontal plane manifests itself, not infrequently making it necessary to measure vertical angles by any means at hand and to correct slope measurements in the office without the knowledge of the client.

Case (3) is an extension of case (2), with the boundary survey checked by numerous crosslines. In this case, a much closer adjustment is possible.

Unfortunately, the writer's notes are stored "for the duration." It would be of interest for some country surveyor to produce a tabulation of his work, showing the accuracies attained under fire (sometimes literally), as set forth against the value of the land surveyed. All credit is due the many honest and efficient men in all parts of the United States who give reasonable results under very unfavorable conditions and thereby aid in the upbuilding of the profession, which has been sadly disgraced at different times and places by men who are neither efficient nor honest.

W. H. RAYNER,[3] M. AM. SOC. C. E.—Careful accounts of surveying procedures, and analyses of the results obtained, are meager and it is gratifying to have such a report by Mr. Bauer.

It well exemplifies the fact that, by proper attention to the more important sources of error, the accuracy of surveys, using ordinary equipment, and at small additional expense, can be greatly increased over the crude results so often obtained.

There are no very definite criteria for comparing the merits of the different surveying instruments, and it has become customary to use the least count of the vernier to designate the character of the instrument used. This is unfortunate because there are wide differences between transits having the same vernier count; also, many transits having 1′ verniers are superior to others with 30″ verniers.[4] The better instruments yield better results with such a saving in time that it is poor economy to use any but the best quality on surveys of any considerable extent.

The use of the "probable error" for two observations as computed by Eqs. 2 and 4, and as described under the heading "Tabulations of Linear Readings," is scarcely justified. This quantity is based on the assumption that a normal distribution of the accidental errors (residuals) of a series of observations is under investigation, and such a distribution can be obtained only where a considerable number of observations are used. It is certainly dubious practice to apply the formulas to a series of less than ten observations.

[4] "Two Investigations on Transit Instruments," by W. H. Rayner, Eng. Experiment Station, Univ. of Illinois, Urbana, Ill., 1938.

It is stated that "The probable error in a single reading of a 1-min transit is ± 25″ (see heading "Findings of Fact from Tabulations," Item (*f*)), but it is not clear under just what conditions this value was found. In particular, an important factor is the reading lens that was used. The writer found in his investigations[4] that, in comparing the results of reading angles with and without a reading lens, the probable error of single readings with the naked eye was reduced about one half when a three-diameter lens was used. It was also found that a large part of the error of single readings of angles is caused by the inability of the observer to set the vernier precisely at zero. This condition explains, in part, why the errors of reading angles with ordinary equipment are so greatly reduced when the method of repetitions is used.

The analysis of results evidently has not differentiated sufficiently between the effects of accidental and systematic errors. For example, all traverses were run as loops, wherein the effects of systematic errors do not become evident. Thus, if a tape were of incorrect length, all sides would be affected proportionately, and the calculated error of closure would in no way be affected by this condition. Also, a constant error in the measurement of the temperature would produce a like effect. Further, the duplicate measurement of a line under the same conditions will not reveal the presence of any systematic errors. This fact probably accounts for the fact that the average accuracy of lines measured in different years was less than that for lines measured forward and back on the same day (see Fig. 3).

Accidental errors are compensative in their effects, and hence the errors as expressed in this report should be smaller for a large number of observations than for a few. This is exemplified by the fact that the accuracy found in taping long lines was greater than for short lines (curves 6 and 7, Fig. 3). This latter consideration is not verified, however, in the case of traverse closures, for no significant difference was found for traverses of different lengths. This unusual result seems to call for some explanation. It is very probable that the computed errors of closure would be larger if the traverses had closed upon each other, instead of being run as closed loops.

It would seem that, where so much care was used in measuring the distances, reference would be made to the U. S. Bureau of Standards to determine the true lengths of the tapes used. The fact that two tapes are of the same length is not complete evidence that they are correct. Their true length is never known until they have been compared with the United States standard, or with a "standardized" tape which has thus been compared.

The effects of the combined errors in distance and angle measurements in traversing are scarcely as simple as that indicated by Eq. 5. The writer attempted an analysis[5] of these effects in 1928. The relations between the linear and angular errors are complex and, in general, their effects must augment each other, so that the total error of closure is larger than the effect of either one taken separately.

---

[5] "Specifications for Transit Traversing and Stadia Leveling," by W. H. Rayner, *Transactions*, Am. Soc. C. E., Vol. 94 (1930), p. 679.

Considering the foregoing remarks, the following comments may be made about the conclusions offered by the author:

(*a*) The analysis in the sixth paragraph preceding Eq. 5 leads to conclusion (2)—namely, that "Retaping a line, forward and back, under average conditions, adds nothing to actual accuracy." This analysis is faulty in that it disregards the effects of systematic errors that would appear in measurements made at different times but not in repeated measurements made under the same conditions. In other words, it is probable that the true errors in the measurements made on the same day are larger than the errors indicated by the duplicate measurements. If so, conclusion (2) cannot be justified by the evidence and analysis used. Clearly, as regards the accidental errors involved, the error of the mean of two measurements will be less than that for a single measurement.

(*b*) Conclusion (3) is based on the oversimplified analysis of the relations of the various errors in traversing. It is conceivable that, in a given traverse, the effects of angular errors will reduce the effects of the linear errors, or vice versa, but in general, where the laws of accidental errors are operating, the total error of closure will be comprised of both angular and linear errors and will be greater than the error produced by either class alone.

Philip Kissam,[6] M. Am. Soc. C. E.—Very definitely, the paper by Mr. Bauer is a contribution to the art of surveying. As the author states, too little is known of the actual accuracies obtained in the field in the usual property surveys, or just what can be done to obtain the desired accuracies at the minimum cost. If more surveyors would follow Mr. Bauer's lead by compiling data as he has, there would be no question whatever that accuracies, methods, and instruments would be improved and costs reduced.

Errors in Transit Results.—To analyze Mr. Bauer's conclusions, the writer has classified the errors of the transit as follows:

Major errors in scale reading—
(1) Errors in determining what the scale reads (probable error = r).
Minor errors in scale reading—
(2) Errors in graduation.
(3) Errors due to play between the inner and outer spindles.
Major errors in pointing—
(4) Errors due to lateral refraction.
(5) Errors due to the positions of the instrument and signals (including phase). The probable error of Items 4 and 5 is h. The two types cannot be separated using the data given.

---

[6] Associate Prof., Civ. Eng., Princeton Univ., Princeton, N. J.

(6) Errors due to not pointing the cross hair on the apparent signal (probable error = p).

Minor errors in pointing—

(7) Errors due to temperature changes in the instrument and tripod.

(8) Errors due to lack of adjustment of the instrument.

(9) Errors due to play in the slide and the trunnions and errors in optics.

(10) Errors due to lack of verticality of vertical axis in setup.

(11) Errors due to play between the outer spindle and the leveling head.

This classification depends on the assumption that the transit is in good working order and that proper operational procedure is used.

In this discussion only the major errors will be considered as the minor errors are negligible under the conditions stated.

Mr. Bauer has determined the accuracy of a single reading of a 1′ transit by tabulating 176 sets of angles. In each case the first reading and the mean of six turns were recorded, together with the difference between the first reading and the mean of six. The mean difference of the entire 176 angles tabulated was found to be 21″. According to the theory of errors the probable error would be: 0.848 × 21″ = 17.8″.

It will be seen that this error E_6 is made up as follows:

Referring to Items 1, 4, 5, and 6, "h" is not present as each measurement was made at one time and with the same positions for the signals and the instrument. Since each pair of observations was made at the same time it is assumed that the lateral refraction was also constant; thus:

$$E_6 = \tfrac{1}{6}\,(k\,r_1 + r_6 + p_1 + p_2 + \cdots + p_{12}) \qquad (6)$$

in which E_6 is the actual error of the mean of six repetitions, and k is the ratio between the error in setting the vernier at zero and the error of reading a 1′ transit to 30″. If E_1 is the actual error of the first reading:

$$E_1 = k\,r_1 + r_2 + p_1 + p_2 \qquad (7)$$

and

$$E_1 - E_6 = \tfrac{5}{6}\,k\,r_1 + r_2 + \tfrac{5}{6}\,p_1 + \tfrac{5}{6}\,p_2 - \tfrac{1}{6}\,(r_6 + p_3 + p_4 + \cdots + p_{12}) \qquad (8)$$

The probable value of Eq. 8 is:

$$17.8 = \tfrac{1}{6}\,\sqrt{(25\,k^2 + 37)\,r^2 + 60\,p^2} \qquad (9)$$

Mr. Bauer finds the probable error of a set of six turns to be 3.8; hence:

$$3.8 = \tfrac{1}{6}\,\sqrt{k^2\,r^2 + r^2 + 12\,p^2} \qquad (10)$$

Solving Eqs. 9 and 10 simultaneously:

When k =	r =	and p =
0.3	16.2	4.4
0.5	15.5	4.3
0.8	14.0	4.0
1.0	13.0	3.9

Assume the third set of values as correct ($k = 0.8$).

It is possible to determine h. Mr. Bauer has determined the probable error of an angle measured by six repetitions when the measurements were made at different times. Such an error includes h. The value determined is 7.0″. Therefore, $7.0^2 = 3.8^2 + h^2$; and $h = 5.9''$. If there is no lateral refraction and the observer can assume that the error in position of the instrument is one half that of the signal, the angular error due to a setup s is $5.9 = \sqrt{2\,s^2 + 2\,(2\,s^2)}$; and $s = 1.89''$.

Since the average length of line is 700 ft, the probable error in position is expressed as follows: $d = \sin 1.89'' \times 700 = 0.0066$ ft, in which d is the error in setting up the transit.

This computation results in the following probable errors in angle determination:

r (reading scale) = 14.0″
0.8 r (setting, zero) = 11.0″
h (position of transit and signals at 700′) = 5.0″
p (pointing on apparent signal) = 4.0″
d (transit position) = 0.0066 ft
2 d (signal position) = 0.0132 ft

These depend on two assumptions. The first is that the vernier can be set at zero with 0.8 as the error of reading the scale. The second is that the error of the signal position is twice the error of the transit position.

There are no data in Mr. Bauer's paper from which can be deduced the decrease in the probable error that would result from reading the minute transit to 15″ or the effect of finer graduations. It is the opinion of the writer that:

1. There is a considerable reduction in probable error when the vernier of a 1′ transit is read to 15″. This procedure has been followed since 1933 by the New Jersey Geodetic Control Survey with considerable reduction in rejected angles.

2. The fineness of graduation has little effect on the accuracy, the accuracy being chiefly a function of the clarity of the graduation as presented to the observer.[7]

Accuracy of Linear Measurement.—Mr. Bauer has given the probable errors of linear measurement for immediate retaping and for retaping at a later date. As he states, this is not based on comparisons with precisely measured high-accuracy surveys. As the accuracy of taping for a given field procedure depends chiefly on tension, temperature, slope, and tape calibration, retaping by the same party on the same day with the same spring balance gives a poor determination of the accuracy, and, as Mr. Bauer points out, is of little practical value except to pick up blunders. The probable error for this condition is given as 1 : 22,800 or 0.0000439, which corresponds to an angle of 9″.

---

[7] "Accuracy of Transit Work Depends on Clearer Circle Graduations," by Philip Kissam, *Engineering News-Record*, April 10, 1941, p. 51.

From the theory of errors (which Mr. Bauer quotes) the following is evident: Probable error $= 0.954 \frac{\text{Total error}}{2}$. Hence, the total error or accuracy for linear measurement is 1 : 10,880.

Traverse Accuracies.—It would seem that when traverses are measured the field procedure should be such that the probable error of the transit would be about equal to that of the linear measurements, as Mr. Bauer suggests. If the angles were measured once with the telescope direct and the measurement repeated once with the telescope reversed (indicated herein as 1 DR); and if both verniers were read each time, the expression for the probable error of angular measurement would be $\frac{1}{2}\sqrt{\frac{1}{4}(k^2 + 3)\, r^2 + 4\, p^2}$. Substituting the values computed, the probable error is 7.78″.

Introducing the errors of position of signals and transit, the resulting accuracy is $\sqrt{7.78^2 + 5.9^2} = 9.8''$. This probable error corresponds very closely with the probable error of linear measurement found by Mr. Bauer, which is the equivalent of an angular accuracy of 9.0″. Thus, where an average accuracy of 1 : 10,000 for a traverse is required, the angles should be measured 1 DR, both verniers should be read, and the usual methods of distance measurement used. Such traverses would have an accuracy of between 1 : 5,000 and 1 : 15,000.

If higher accuracies are desired, the method of taping should be improved. If it were desired to obtain traverses having an accuracy of 1 : 25,000, a probable error of 1 : 52,000 would be necessary. The use of the plumb bob would have to be eliminated. Probably this could be obtained in commercial work by using a 300-ft tape fully supported on some surface, like a sidewalk or street pavement, using a thermometer and spring balance, and running a rough profile over the tape for slope corrections. When such a procedure is used the accuracy of measurement will usually attain better than 1 : 25,000, having a probable error of 1 : 52,000.

A probable error of 1 : 52,000 corresponds to about 4″ of arc. To obtain a probable error of 4″ in the transit work would require a considerable improvement in the centering of signals and possibly in the transit itself.

The desired results could be obtained if the signals were designed to have no phase and the work could be performed at any time when there was at least some haze or cloudiness so that the lateral refraction would be reduced, and if the signals and the transit were set so that the probable error of their positions was 0.005 ft. Under these conditions $h = \sqrt{4\, s^2} = 2\, s$; but, at 700 ft, $s = \frac{0.005}{700} = 1.40''$, and $h = 2.8''$.

Transit accuracy also would have to be maintained so that a lower probable error would result than Mr. Bauer found to be the rule.

To obtain this accuracy it is suggested that one set of 3 DR be used, reading both verniers at the beginning and end of the set. Then, the probable error is $\frac{1}{6}\sqrt{\frac{1}{4}(k^2+3)\,r^2+12\,p^2} = 3.20''$. Combining the error of the transit operation and the error of the positions of the transit and the signals, the probable error of angle determination would be $\sqrt{(3.20)^2+(2.8)^2} = 4.2''$. This is practically low enough.

This error would be reduced, of course, by using lines of more than 700 ft so that a reasonably good balance between transit accuracy and taping accuracy would be maintained. Assuming that transit errors and taping accuracy affect the traverse equally, the probable error of such a traverse would be about 1 : 50,000, and the accuracy about 1 : 24,000.

Conclusions.—1. Assuming that Mr. Bauer's traverses represent the usual traverses run by good land surveyors, the accuracy to be expected is between 1 : 5,000 and 1 : 15,000.

2. The transit work is of a much higher degree of accuracy than the taping and so long as the present method of taping persists there is no advantage in turning the angle more than 1 DR, using both verniers.

3. If high-grade traverse work is required, an accuracy of 1 : 24,000 can be obtained with little, if any, increase in cost if a 300-ft tape is used and the angles turned 3 DR reading both verniers.

These recommendations are based on the assumption that a better target is used than is ordinarily found in practice and that the noon hours on clear days be avoided for angle measurement.

It will be noted that in determining the order of accuracies of traverses, Mr. Bauer has assumed that *Manual No. 10* uses a "probable" error in specifying the order of accuracy. It is the belief of the writer that by "error of closure" is meant the total error divided by the total length, a value which is much more difficult to obtain. For example, the average position closure required for first-order traverse is 1 : 35,000. To obtain this accuracy the average probable error would have to be 1 : 73,500.

GEORGE D. WHITMORE,[8] M. AM. SOC. C. E., C. C. MINER,[9] ASSOC. M. AM. SOC. C. E., AND W. O. BYRD,[10] ESQ.—An interesting approach to the complex subject of traverse accuracies is contained in this paper. The writers have long felt that too much emphasis has been placed on the "just-happened" closure of the entire loop, and not enough on designing measuring instruments and measuring procedures that will insure uniform precision for each and every tangent of the entire traverse. Experience shows that traverses having circuit closures of high order, such as 1 : 10,000 or 1 : 20,000, may conceal errors, in the individual courses, of the order of 1 : 1,000. The writers believe that the accuracy specified for a traverse loop or line should be an indication also of the approximate precision of each individual course in the entire line.

Traverse does not have as many rigid geometric checks available as does triangulation, and for that reason safeguards against blunders are imperative. Within the limits of accuracy desired in the traverse, known systematic errors should be eliminated, and measuring procedures should be used which will minimize the unknown systematic and accidental errors. Measuring instruments should be used that will provide the required accuracies most economically.

[9] Civ. Engr., Maps and Surveys Div., TVA, Chattanooga, Tenn.

[10] Associate Mathematician, Maps and Surveys Div., TVA, Chattanooga, Tenn.

Unless consideration is given to some of the systematic taping errors, third-order traverse accuracy can be attained only under exceptional circumstances. For instance, any one of the following conditions would result in systematic errors that would equal the limits for third-order traverse accuracy (1 : 5,000):

(*a*) If the actual length of a 100-ft tape differed by as much as 0.02 ft from the true length, a systematic error of 1 : 5,000 would result. Such a change in length may be caused by stretching or kinking.

(*b*) Under certain conditions a systematic error of 5 lb in the tension applied to the tape would result in a systematic error of 1 : 5,000.

(*c*) If the actual temperature of the tape is in error by 30° F, a systematic error of 1 : 5,000 would result. Such an error may result from applying no temperature correction, or, under extreme conditions, from applying the temperature of the air rather than of the tape itself.

There are, of course, other systematic taping errors, the accumulated effect of which may be appreciable.

The need for reducing systematic taping errors is felt immediately when the traverse runs between two previously fixed points, such as high-accuracy triangulation stations, or is part of a traverse net run under varying weather conditions by two or more parties using different measuring equipment and procedures. These errors, obviously, will not ordinarily be felt when dealing only with a single traverse that is run in a loop, originating and terminating on the same point, such as described by the author.

The attempt to eliminate systematic errors, both linear and angular, will influence, to a large extent, the measuring procedures and instruments used; a study of surveying accuracies is incomplete until the effects of such errors are considered. Systematic angular errors fortunately can be largely eliminated by proper observing procedures and by distributing angular closures before computing latitudes and departures.

The writers believe that accidental angular errors have a considerable effect on the quality of a traverse, but that accidental taping errors, because of their more nearly complete compensation, have a much lesser effect and account for only a small part of the total traverse closure. The effect of accidental angular errors can be reduced, however, by means of any or all of the following safeguards: (1) Frequent azimuth control lines through triangulation; (2) frequent astronomical observations; and (3) use of long azimuth control lines, which span several of the shorter, directly taped courses.

The writers would like to add the following thoughts to the three questions posed at the end of the paper:

A. The limiting of the closure error is not adequate to assure a desired traverse accuracy. The writers believe that the specifications should include the measuring procedures and instruments to be used, so that each individual tangent will be of the required accuracy.

B. Smaller plate graduations on transits for city work are justified primarily for reasons of economy, because the desired angle accuracy can be obtained with a fewer number of turns.

C. The writers find little to criticize in the design of the newer transits now on the market. Of course, improvements will continue to be made; however, they will probably be in the direction of greater accuracies and more stability.

G. BROOKS EARNEST,[11] M. AM. SOC. C. E.—Far too often the question uppermost in the mind of the practicing, private surveyor is that of profit alone, rather than profit plus self-satisfaction resulting from assurance of relative accuracy of the individual surveys. Obviously, engineering economy dictates the essential equipment, together with the methods of operation and order of procedure for various classifications of surveys executed by the private surveyor. Therefore, specifications are usually neglected—which can be contributed largely to the existing multifarious public and private control surveys.

When one undertakes to make an exhaustive search of survey records through an accumulation of field books covering a practice of fifteen years or more, he is to be commended highly. Would that other practicing surveyors might similarly correlate their work, if for no other reason than to determine their budget of accuracies throughout stages of their practice.

In all probability, there would be little similarity between published accuracy curves of a score of territorily scattered, private surveyors. Many reasons contribute to this fact; such as: Instrumentation, individual (unique) methods of operation, topography, existence or nonexistence of precise control, taping procedure, and climate. Nevertheless, the underlying thought in such research is to inculcate "precision thinking" among those in the field of surveying—not with the intent that an estate survey in the suburbs should be executed with the same degree of precision as a "downtown" survey where property is worth several thousand dollars per front foot, but wholly with the idea of impressing the private surveyor with the value of uniformity of specifications for individual types of surveys.

The author's results represented by curves, (3) through (8) (Figs. 2, 3, and 4), are indicative of experienced personnel and painstaking field execution. However, to one who is experienced in traverse surveys of first-order and second-order nature and with the knowledge of the pitfalls encountered even with the use of 10″ repeating instruments, taping bucks, etc., to comply with the control precision specified, it is difficult to conceive the respectable percentage of high-order results from commonly called "third-order" methods of field operations. Of course, without precise control, loop closures must be relied upon to compute the probable error of closure, and there is the possibility of compensating errors fortunately producing occasional, exceptional order of precision.

Relative to angle observations and taped distances between two monuments of the common "garden variety" street intersection type, taken several years apart, there would naturally be no pattern of mean probable error (especially north of the Mason and Dixon Line). Furthermore, geological conditions, frost conditions, and depth of monument would affect such comparison measurements differently in cities widely separated in latitude. Such "lapse time-measurement" curves, therefore, conform strictly to individual conditions and are meaningless unless observations are between so-called permanent monuments that have their support below the frost line and are low in susceptibility to frost action.

---

[11] Associate Prof., Eng. Surveying, Case School of Applied Science, Cleveland, Ohio.

Uniformity is the biggest factor in making related studies of the private, practicing surveyor. The Society's Surveying and Mapping Division recognized this fact when, in 1928, it formed the Committee on City Surveys and directed this Committee to draft a manual "for the purpose of describing the various divisions of the complete City Survey, to furnish specifications for it, and to make detailed recommendations as to accepted technical methods." The result of this Committee's study and research was published in 1934 as *Manual of Engineering Practice No. 10,* entitled "Technical Procedure for City Surveys." The scope of this manual dwelt chiefly on control surveys of highest order. Later, in 1940, due to increased importance in the subject, *Manual of Engineering Practice No. 20* was published entitled "Horizontal Control Surveys to Supplement the Fundamental Net." These manuals represent approximately ten years of active committee work in drafting the universally recommended procedures for the several orders of control. Therefore, it behooves the practicing surveyor, who desires to stay abreast of the field, to conform to procedures recommended in these manuals and thereby make possible tangible comparisons of individual accomplishments in the future.

S. A. BAUER,[12] ASSOC. M. AM. SOC. C. E.—The writer is indebted to Colonel Coe; Professors Earnest, Kissam, and Rayner; and Messrs. Whitmore, Miner, and Byrd for their kind discussions of this paper. The discussions have been helpful in suggesting new approaches to this study of traverse accuracies.

Professor Rayner is correct that Eq. 5 (which attempts to view the overall picture) tends to oversimplify the problem in relation to the individual traverse. Curves 4, 5, and 8, Fig. 5, offer a truer picture of the problem as applied to the individual traverse than that previously presented in Fig. 4, since the conditions within a specific traverse are more nearly met by curve 5 than by curve 6. In Fig. 5, curve 9 represents the value of the square root of the sum of the squares of the linear and angular errors (reduced to the common unit of one part in x thousands) at the various frequencies. In the normal ranges of accuracy, there is a marked agreement between calculated curve 9 and traverse curve 8. This would seem to indicate a compensating effect of the linear and angular errors within a traverse.

However, the linear errors referred to are the probable errors in the measurement of single lines, and the angular errors similarly are the probable errors in the observation of single angles. Curve 9 then might be the probability curve of accuracy for the setting of a single point by angle and distance as well as the curve for traverse accuracy. If so, then the number of sides, and therefore the length of a traverse, plays no part in the accuracy of closure.

This contradicts much that has been written, and it is particularly contradictory to Professor Rayner's 1928 study of the problem,[5] wherein the accuracy of traverse closure is given as a function of the length of traverse.

---

[12] (Bauer Surveys Co.), Cleveland, Ohio.

The writer finds no relationship of traverse accuracy to length of traverse but only to mean side length. Professor Rayner properly asks for explanation. On this point, further investigation has proceeded as follows: Seven cases of from two to six connecting traverse loops with the same general conditions were studied; in none of the seven cases was the over-all or outside loop closure better than the best smaller inside loop closures of which it consisted; in three cases, the outside loop closure was equal or inferior to the poorest inside loop closure; in seven cases, the outside loop closure was better than certain individual loops within itself; and, in eleven cases, the outside loop closure was inferior to certain individual loops within itself.

Six other cases of two or more interlocking traverses, having the same general topographic conditions but without an over-all outline closure, were examined. In two cases the longest loop of its group had the best closure of the group; four cases occurred in which the longest loop of a group had the poorest closure of the group; in eight cases, the longest loop had a better closure than some of the smaller loops within its group; and, in five cases, the longest loop of a group had poorer closures than others within the group.

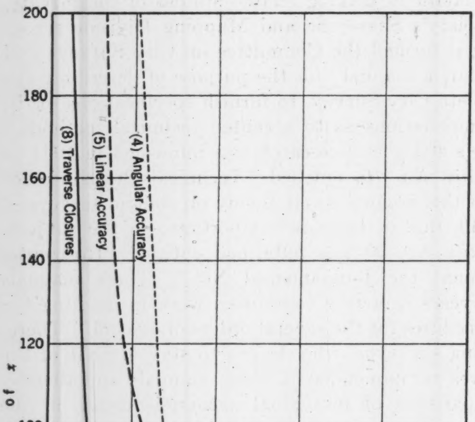

FIG. 5.—TRAVERSE MEASUREMENT AND ANGLE ACCURACIES (EXPRESSED AS ONE PART IN x THOUSANDS)

The foregoing study of thirteen groups of traverses (each traverse being comparable to the others within its group as to terrain, side length, etc.) indicates no relationship between traverse closure and traverse length. This study would seem to indicate, also, that the compensation of errors does not extend throughout a traverse, that increased length of traverse will not help the closure, that the length of the traverse side, rather than the traverse length, affects the closure, that the compensation of errors occurs within a single side, but that in a traverse the side error becomes systematic.

The writer is not ready to state that this relationship extends to all instrumentation and procedures. These findings only can be attributed to the equipment and procedure used in this paper, since the limit of accuracy of the instrumentation may have been reached at approximately the length of a mean line and that additional length may not add to accuracy any more than unlimited reobservation of a measurement will increase the accuracy of the measurement indefinitely. (It will increase only the accuracy of the value of the probable error.)

Expressed differently, the hypothesis is offered that, within a traverse, errors combine as compensating errors to a point (probably determined by the instrumentation and procedure) and then become fixed as a systematic error, increasing with the length of the traverse, and thereby establishing an accuracy, expressed in terms of error per traverse length, fixed at the point where compensation ceases.

Professors Earnest, Kissam, and Rayner in various manners raise the problem of the difference between loop closures, which close upon themselves, and position closures between fixed stations previously established by precise control.

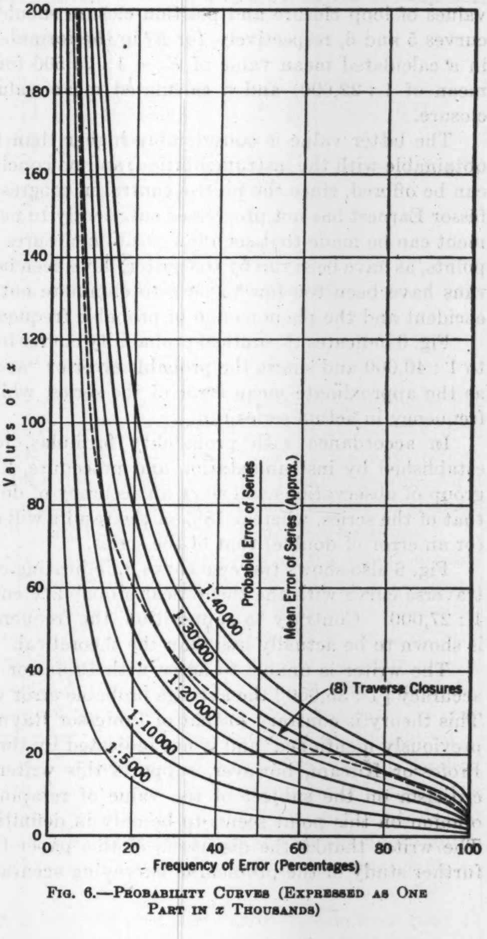

FIG. 6.—PROBABILITY CURVES (EXPRESSED AS ONE PART IN x THOUSANDS)

Although this paper is primarily concerned with actual accuracies that have been obtained in the regular business of a practicing surveyor in a territory as yet not covered by a precise control, it should not be improper (beyond the bounds of possibility) to project the same reasoning into channels indicated by the facts disclosed.

Therefore, if (as seems to be the case) traverse closures are in general equal in value to the square root of the summation of the squares of the mean linear and angular errors of the instrumentation and procedure used, the relative values of loop closure and position closure should be indicated by the use of curves 5 and 6, respectively, for E_1 in the formula $E_t = \sqrt{E^2_a + E^2_1}$ resulting in a calculated mean value of $E_t = 1 : 21{,}500$ for loop closures (an observed mean of 1 : 22,600) and a calculated mean value of 1 : 18,000 for position closure.

The latter value is considerably higher than that generally recognized as obtainable with the instrumentation, and no conclusive proof of the hypothesis can be offered, since the precise control in progress under the direction of Professor Earnest has not progressed sufficiently to permit such proof. The statement can be made that such few position closures between established transfer points, as have been run by the writer, have been better than 1 : 20,000. These runs have been too few to date to eliminate entirely the possibility of mere accident and the phenomenon of probable frequency of error.

Fig. 6 indicates theoretical probability curves for accuracies of from 1 : 5,000 to 1 : 40,000 and shows the probable error or "accuracy" of each series as well as the approximate mean error of the series, which occurs at about the 60% frequency in actual series run.

In accordance with probability formulas, for any prescribed accuracy established by instrumentation and procedure, 27% of the results of a large group of observations will show an accuracy of double (or an error of one half) that of the series, whereas 18% of the results will show an accuracy of one half (or an error of double) that of the series.

Fig. 6 also shows traverse curve 8, indicating close conformity of the actual traverse curve with the theoretical probability curve for an accuracy of about 1 : 27,000. Contrary to supposition, the frequency of extremely small errors is shown to be actually less than the theoretical.

The writer is unable to agree with Professor Kissam that "to obtain this accuracy [1 : 35,000] the average probable error would have to be 1 : 73,500." This theory is contrary to that of Professor Rayner as elaborated in his paper previously mentioned[5] and is not indicated by the results of these tabulations. Professor Kissam, however, supports this writer against Professor Rayner's criticism on the subject of the value of retaping a line. The difference of opinion on this point seems to be only in definition of terms and not in fact. The writer thanks the discussers of this paper for new thought to apply to further study of the problem of surveying accuracies.

EARLY CONTRIBUTIONS TO MISSISSIPPI RIVER HYDROLOGY

By C. S. Jarvis,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Robert Follansbee, R. W. Davenport, Charles Senour, John C. Hoyt, George O. Guesmer, H. T. Cory, and C. S. Jarvis.

Synopsis

Recent research in runoff characteristics of the Mississippi River basin has disclosed certain values among the early records which had apparently been neglected, if indeed they had ever been recognized outside the group responsible for assembling them. These data generally are to be found in some form or other in old reports and records of the War Department, mainly in publications of the Corps of Engineers and the Mississippi River Commission.

The fragmentary hydrologic data of the earliest record periods are assembled in this paper. They are extended by derivation, estimation, or comparison with related data from neighboring stations, and tentatively integrated into a continuous record covering 122 years, ending in 1938. Incorporated within the record are the discharge determinations for the 33 years ending with 1860, as published by the late A. A. Humphreys, Hon. M. Am. Soc. C. E., and Henry L. Abbot, with such adjustments as were found necessary to conform to the hydrographs of calendar years. Likewise, other results, official or unofficial, published or unpublished, were taken into consideration in compiling these basic hydrologic data. A sharp distinction has been made between the official quantities and those derived or estimated. However, such controls and cross references as are available have been used freely, so that the final results, as here submitted, are as nearly beyond challenge as it seems practicable to obtain at this time.

Trends of both precipitation and the resulting runoff depths from year to year, or from decade to decade or other record segment, are disclosed, with fair correlation generally for the 5-yr or longer period means, and to a lesser extent, on an annual or even a monthly basis.

Note.—Published in March, 1942, *Proceedings*.

[1] With Office, Chf. of Engrs., Washington, D. C.

LOWER MISSISSIPPI RIVER DISCHARGE

Heretofore, the oft-repeated inquiry concerning the actual discharge of the Mississippi River in its lower course has brought unsatisfactory results according to the writer's observation; yet the observed, computed, and estimated discharge quantities have been recorded for 33 of the 43 years, 1818 to 1860, inclusive.[2] The fact that these discharge quantities are expressed in cubic feet per year, and thus involve trillions, should be no barrier against their use. Division by the number of seconds in a calendar year readily reduces the quantities to yearly average discharge in cubic feet per second, as shown in Table 1. The use of hydrographs and tabulations of gage heights assisted in the apportionment of discharge, month by month, to conform substantially with the respective yearly quantities. Moreover, both large-scale hydrographs and daily discharge quantities are available for practically the entire years 1851, 1858, and 1859, representing the most notable flood years of the Mississippi River, within the detailed record period up to that time, at two or more stations on the lower river. Likewise, the same information is available for 1852, and for parts of other years at various stations on the main river and its tributaries, in addition to some 30 years of river-stage records, 1817 to 1860, inclusive, depicted on smaller scale for publication in *Professional Paper No. 13*, and recently generalized and further reduced for inclusion in Fig. 1. This record was compiled from several sources:[3, 4] Reports of the Mississippi River Commission;[5] records of rainfall, river-stage and flood phenomena, compiled

from Recent Rating Curves.

The meticulous care with which the observers recorded information such as wind and weather conditions that might possibly affect the operation of the primitive velocity-measuring apparatus (mainly multiple floats and early types of current meter), the faithful portrayal of results showing the influence of the rising as opposed to the falling stage of each major flood event, the recognition of inherent limitations as to attainable accuracy for individual measurements—all are earnest approaches toward, if not the stepping-stones leading to, the more rigorous standards attainable with improved apparatus and methods developed during recent years. Quoting Messrs. Humphreys and Abbot:[6]

> "It is evident that the condition of the river, whether rising or falling, makes a great difference in discharge at any given stand; but it is equally evident that a mean line between these two extremes can be drawn that shall form the basis of a table by which the annual discharge can be deduced from the recorded gauge-readings. For any given day, its indication will be erroneous, but for the entire year, which includes both the rising and the falling branches of the curve, it will be sufficiently accurate * * *."

The difficulties encountered with surface floats, subject to deflection or acceleration due to wind velocity, naturally led to the adoption of multiple floats, largely submerged, and of rods so weighted and adjusted as to maintain them nearly submerged and vertically suspended, supporting small flags above the surface for observation. By such means, Messrs. Humphreys and Abbot developed information regarding depth-velocity relations closely in accordance with the most advanced thought and adopted theories of recent years, as evidenced by the parabolic velocity curves presented by them.[7] Likewise, they presented evidences of a rigorously scientific approach to determinations of both mean and maximum velocities in terms of surface velocities or of those observed some 5 ft below; even a forerunner of the familiar reduction factor of 0.80 or thereabouts, by which observed surface velocity may lead to an approximate value of mean velocity for the station.[8] Abundant proof is to be

STAGES FROM ALL AVAILABLE RECORDS, 1770 TO 1939

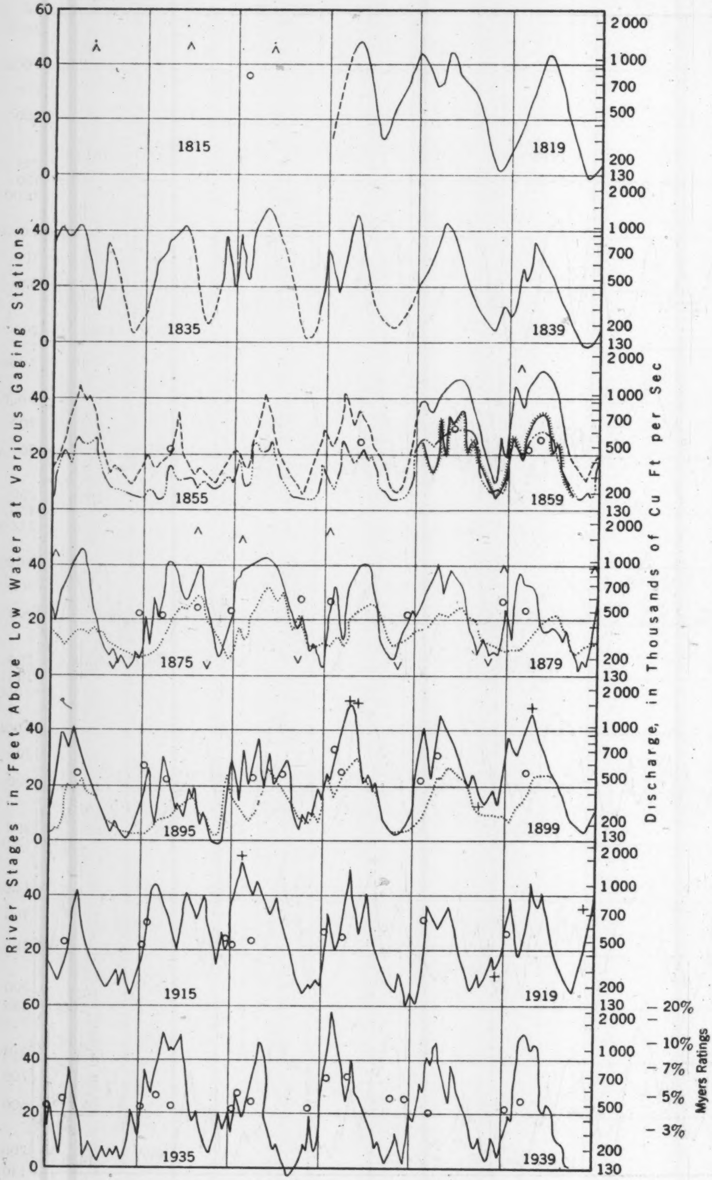

FIG. 1.—*Continued*

found in the associated text of fair agreement between quantities determined by formula and by observations.

A review of the specific examples in the same report for which detailed calculations are recorded should not fail to impress an unbiased investigator with the idea that those early measurements of stream discharge are beyond challenge, within the reasonable limitations as to accuracy, inherent in their equipment, methods, and working conditions. Whenever hydrologists have had to rely upon quantities determined by slope-area methods, depending on high-water marks observed some days following the passage of a flood peak, whether the event was last month, last year, or 100 years ago, they have occasion to regret the absence of actually observed velocities. Even the progress of uprooted trees in midstream—or better, largely-submerged floats, properly spaced, and observed by theodolites over measured courses in accordance with those early practices—might give results at least more convincing, if not more reliable, than those ordinarily expected by slope-area methods; yet the latter in skilful hands may provide fairly acceptable approximations—often the only available data as to some of the flood-peak discharges officially published during recent years.

SEDIMENTATION AND RELATED STUDIES

Other basic problems considered in *Professional Paper No. 13* include the development and effects of cutoffs, levee systems, storage reservoirs, spillways, and lateral overflow areas. Also included are the proportion by weight and the distribution of both bed load and sediment in suspension, the latter varying, for the 12-month period beginning February, 1851, from $\frac{1}{681}$ to $\frac{1}{6,383}$, or an average of $\frac{1}{1,808}$ for the year.[9] Expressed in parts per million by weight, these fractions reduced to 1,467 ppm, 157 ppm, and 553 ppm, respectively, for Carrollton, La., as contrasted with the tentative estimates for the following year—namely, 1,748 ppm, 116 ppm, and 690 ppm. Furthermore, observations extending from March to November, inclusive, 1858, at Columbus, Ky., gave results[10] reducible to 1,493 ppm, 140 ppm, and 757 ppm, whereas those at the Mississippi mouths, taken by George G. Meade (later Major General, U. S. Army) from April to June, 1838, averaged 638 ppm for surface samples, and 785 ppm for subsurface, at depths ranging from 6 ft to 90 ft.

The foregoing observations as to suspended sediment during years of more than normal rainfall and runoff afford interesting comparisons with data published by the U. S. Geological Survey[11] in 1909. These are based on 15 years of sediment determinations by the Corps of Engineers, U. S. Army, and 5 years of determinations by the New Orleans (La.) Water and Sewerage Board, prior to 1907, and one year of determinations at various stations by the U. S. Geological Survey, presumably during years of somewhat less than normal average runoff, such as prevailed in the period preceding 1907. The report shows (see Table 2)[11] that suspended sediment above and below the Missouri River mouth, at Quincy, Ill., and St. Louis, Mo. (Jefferson Barracks), respectively, was increased some eight-fold, or from 119 to 964 ppm, while the dissolved solids remained nearly constant (see Table 2).

DENUDATION—LOCAL AND BASIN-WIDE

Probably the brief chapter on "Denudation," from which Table 2 was obtained,[11] represents the most comprehensive and scientific approach to the problem of which there is evidence, up to the date of its publication. Among the items of interest and value are those purporting to represent the average river discharges and proportions of solids throughout the periods of available record. The fairly consistent relationships between such discharge and sediment computations or estimates, and those developed in connection with this paper and associated research projects, afford at least partial confirmation from officially accepted and published quantities.

One of the most serious errors that might readily result from a casual use of such data would be the assumption that it requires centuries of erosion and runoff to denude the soil a single inch, when it is well known that a day of intense rainfall or of rapid thawing, or a series of storms, may displace recently disturbed, unstable, unprotected soil on moderate slopes to a depth of not only an inch, but occasionally several inches under only normal concentrations of flow. It is well known that soil on sloping shale or other smooth surfaces may slide in its entirety when the plane of cleavage becomes saturated, so that the volume of solids moved locally, for short distances, may far exceed the volume of water releasing it. Thus, the actual depth of local denudation in a semi-arid region, on steep, relatively bare slopes, might represent a large percentage of the actual rainfall and might far exceed the depth of runoff from the entire basin, which usually represents only small percentages of rainfall.

It follows from the foregoing that the solids transported by the Mississippi River and delivered into the Gulf of Mexico are but finely divided samples of the total erosional products—the dissolved or flocculent or other readily suspended portions of the disturbed soil mantle. The heavier and coarser materials, along with varying percentages of the finer elements, are strewn along the flood plains, valley floors, and network of drainage channels, awaiting the next turbulent flow to exact a further toll of easily transported elements.

TABLE 3.—ANNUAL MAXIMUM GAGE READINGS ON THE MISSISSIPPI RIVER AT CARROLLTON, LA.

RUNOFF FROM RAINFALL AND TEMPERATURE DATA

Without those well-organized approaches to river gagings during the early decades of the nineteenth century, engineers would have been deprived of much helpful hydrologic information as well as scientific observations and opinions in related fields. A fair-minded review of the mass of data yielding the average yearly discharges of the Mississippi River at Natchez, Miss., for record periods of early decades[12] cannot fail to impress one with the magnitude and difficulties of the undertakings, and the foresight, determination, and scientific as well as practical accomplishments of those early observers and authors.

The writer's review of those early records disclosed such consistent relationships between rainfall, temperature, and runoff, all in fair agreement with the same observed phenomena during recent years of record, that they provided access to requisite basic data and indicated a method for deriving probable values of Mississippi River monthly average discharge for the years of rainfall record, including the intermittent and fragmentary observations. One can scarcely use the term "non-record" in this connection, inasmuch as some basic data at important gaging stations are available for every year beginning with 1817. Maximum annual stages at Natchez date back intermittently to 1770, and continuously after 1801; and available records of maximum gage heights at Carrollton began in 1811, as shown in Table 3.[13]

---

[12] *Water-Supply Paper No. 234*, U. S. Geological Survey, Washington, D. C., p. 131.

Table 4 shows some interesting relationships between departures from mean rainfall and runoff, year by year, and month by month, all expressed in inches of depth over the entire drainage area above Natchez. (Runoff was either measured or estimated for the Mississippi River at Natchez. Temperature observations were made at St. Paul, Minn., from 1819 to 1837, and at St. Louis, from 1838 to 1877. Precipitation was observed at Marietta, Ohio, from 1817 to 1829, and at additional stations thereafter as they became available with desirable distribution. In 1850, the total was 15 stations; in 1860, 22 stations; in 1868, 27 stations; and in 1873, 45 stations.) The two representative years selected for inclusion were 1850 (above normal), and 1860, with subnormal rainfall and runoff. Thus a yearly excess of 5.5 in. in precipitation produced an excess runoff depth of 1.61 in., whereas the deficiency of 5.8 in. produced a departure of − 1.33 in. in runoff. For the first 61 years of the record, the mean rainfall and runoff departures yearly were + 0.50 and + 0.30 in., respectively, from which it may be logically assumed that the same quantities with opposite signs would apply for the latter half of the record, if worked out on a comparable basis. Results actually computed on a yearly basis, but with the addition of several more rainfall station records, were − 0.35 in. and − 0.27 in. for the 61-yr period, 1878 to 1938.

TABLE 4.—DEPARTURES OF OBSERVED TEMPERATURE, PRECIPITATION, AND MISSISSIPPI RUNOFF FROM RECORD MEANS

(ΔT, ΔP, and ΔR = Departure of Temperature, Precipitation, and Runoff, Respectively)

Month	1850			1860			AVERAGES, 1817 TO 1877		
	ΔT (degrees F)	ΔP (in.)	ΔR (in.)	ΔT (degrees F)	ΔP (in.)	ΔR (in.)	ΔT (degrees F)	ΔP (in.)	ΔR (in.)

February	+2.4	+1.0	+0.37	+2.8	+0.4	−0.06	+0.7	+0.17	−0.03
March	−0.3	+0.6	+0.14	+15.7	−2.2	+0.27	+0.3	−0.14	+0.01
April	−6.4	+0.9	+0.09	+2.9	−0.6	−0.35	+0.6	−0.00	−0.01
May	−3.6	−0.8	+0.23	+5.1	−1.4	−0.29	+0.2	−0.04	+0.05
June	+1.8	+1.3	+0.23	+1.2	−0.8	−0.32	+0.8	+0.24	+0.05
July	+2.0	+0.6	+0.09	+3.3	−0.7	−0.25	+0.7	+0.30	+0.04
August	+4.0	+0.5	+0.03	+0.8	−0.7	−0.11	+0.1	+0.13	+0.07
September	−0.5	−1.4	−0.03	−2.8	−0.3	−0.09	−1.2	+0.01	+0.04
October	−2.2	−0.9	−0.03	+0.1	+0.1	−0.05	−2.2	+0.01	+0.02
November	+2.4	+0.3	+0.05	−4.5	+0.9	−0.07	−1.2	+0.18	+0.02
December	−3.1	+1.4	+0.08	−4.4	−0.1	−0.07	−1.1	−0.02	+0.03
Total	+0.2	+5.5	+1.61	+1.9	−5.8	−1.33	−0.2	+0.50	+0.30

For the month of March, 1860, the influence of the 2.2-in. deficiency in rainfall was more than offset by the unseasonable temperature, the + 15.7° F having released the ice sufficiently to produce an excess depth of 0.27 in. in runoff for that month. Likewise, a rainfall deficiency of 0.8 in. for May, 1850, in combination with a temperature departure of − 3.6° produced a runoff excess of 0.23 in. In many instances the time lag between rainfall and runoff accounts for the excess or deficiency occurring in the following month or year instead of being in the same period as the rainfall.

---

[13] "Report on the Physics and Hydraulics of the Mississippi River," by A. A. Humphreys and Henry L. Abbot, *Professional Paper No. 13*, Corps of Engrs., U. S. Army, 1876, p. 443 and Plate XIV.

Table 5 lists the average rainfall depths for the available stations, to the number of 50, for the entire 122 years of record, together with the departures in both precipitation and runoff, all measured in inches over the drainage basin above Natchez. In general, about 3 in. of rainfall departure produced 1-in. departure of the same sign in runoff. However, there are wide variations from that ratio, and a number of sign reversals.

THE VICKSBURG-NATCHEZ RECORD OF MISSISSIPPI RIVER DISCHARGE

In spite of the 4,900 sq miles excess of drainage area at Natchez as compared with that at Vicksburg, Miss. (representing 0.43% difference), the annual yields should be within 1% of equality. Therefore, they should be almost interchangeable for the early records, if not for the later ones, in view of the admitted uncertainties of stream measurements at their best, requiring a tolerance of some multiple of that difference, according to conditions. Where stream gagings are numerous and of a high standard, it may appear reasonable to take the difference of 1% into account, as has been done for the Vicksburg-Natchez record. Thus, the 122-yr means have reduced to 593,000 cu ft per sec and 599,000 cu ft per sec, respectively. From Table 1, the 33-yr record mean for Natchez was either 614,000 or 617,000 according to the two separate determinations, thus differing by 0.5%, which happens to be the same as the percentage of record-period represented by the two-month difference between those water years and the calendar years. According to Table 6, the first 50-yr mean discharge at Natchez was the maximum attained, or 626,000 cu ft per sec, as compared with 605,000 for the first 100 years, or 602,000 cu ft per sec for the first 110 years. (Table 6 was compiled from the Humphreys-Abbot report; from stages and discharge observations of the Lower Valley of the Mississippi River, January 1 to June 30, 1937; from annual reports of the Mississippi River Commission and the Corps of Engineers; and from Water-Supply papers of the U. S. Geological Survey.)

CONSUMPTIVE USE OF WATER

Obviously the increased consumptive use of water in connection with initial fillings of large storage reservoirs, together with the subsequent diversion for irrigation and other purposes, may account for some of the difference between the first 50-yr mean and the mean discharges for later periods at Natchez. It has been computed and estimated that, as of 1930, some 13,000 cu ft per sec were withheld from the Lower Mississippi River for irrigation alone, exclusive of initial storage and attendant losses.[14]

RELATIVE PERMANENCY OF GAGING SECTIONS

Opinions expressed by Messrs. Humphreys and Abbot as to the aggradation, degradation, or relative permanence of Mississippi River channel sections were evidently based on more than those early determinations, covering some 44 years of intermittent observations and records at various stations. Their several years devoted primarily to the investigation, including residence and field work, must have been supplemented prior to the second edition in 1876, because they were still actively engaged in important professional work, and thus were able to participate in the additions, with nearly a 60-yr record before them. Therefore, it seems evident that they had considerable basis for their opinions, repeatedly expressed in their report, to the effect that in general the Mississippi River bed in its lower course was neither building up nor cutting

[a] A minus sign denotes "deficit."

[b] Values in parentheses were not published in the original tabulation, but were derived from data contained therein.

[c] Average discharge of the Mississippi River at Natchez, Miss., for 122 years (1817 to 1938, inclusive) was about 599,000 cu ft per sec, representing an average yearly runoff depth of 7.06 in.

[d] Using the month-by-month analysis from 27 or 45 rainfall stations for comparison with the succeeding six items.

down, but that the indurated bluish clay through which the channel is carved seems resistant to erosion so long as it remains saturated. They found that the sediment was being swept consistently forward during moderate and high flows, to extend the delta, although local deposition and erosion might occur alternately along the channel. This opinion is certainly confirmed by authoritative observations and expert findings of later date.[15] Such data show only a slight tendency toward scouring the river bed, ranging from 0 to 4%

[a] Cfs = cubic feet per second. [b] Minus sign denotes "deficiency."

for the 20-yr period, 1894 to 1913, and adhering quite closely to the cross-sectional areas and dimensions shown in *Professional Paper No. 13.*[16] Furthermore, all available official data, whether published or unpublished, were summarized and plotted for successive periods in Figs. 2 and 3, for six important gaging stations on the lower river. These show not only the meanderings of the rating curves, but also the near approach to constancy for considerable periods, and particularly in the lower segments of such curves.

[a] Discharges marked thus: [a]—are Vicksburg readings, and the remainder are Memphis readings. Values in parentheses are unofficial or estimated quantities. [b] Additional floodway and valley storage discharge. [c] Maximum river and floodway discharge. [d] Item 1 represents the record-period maximum for 40 years or more preceding 1858.

Further evidence concerning the progressive minor changes in rating curves, showing the relation of gage reading to river discharge, is offered in Table 7.

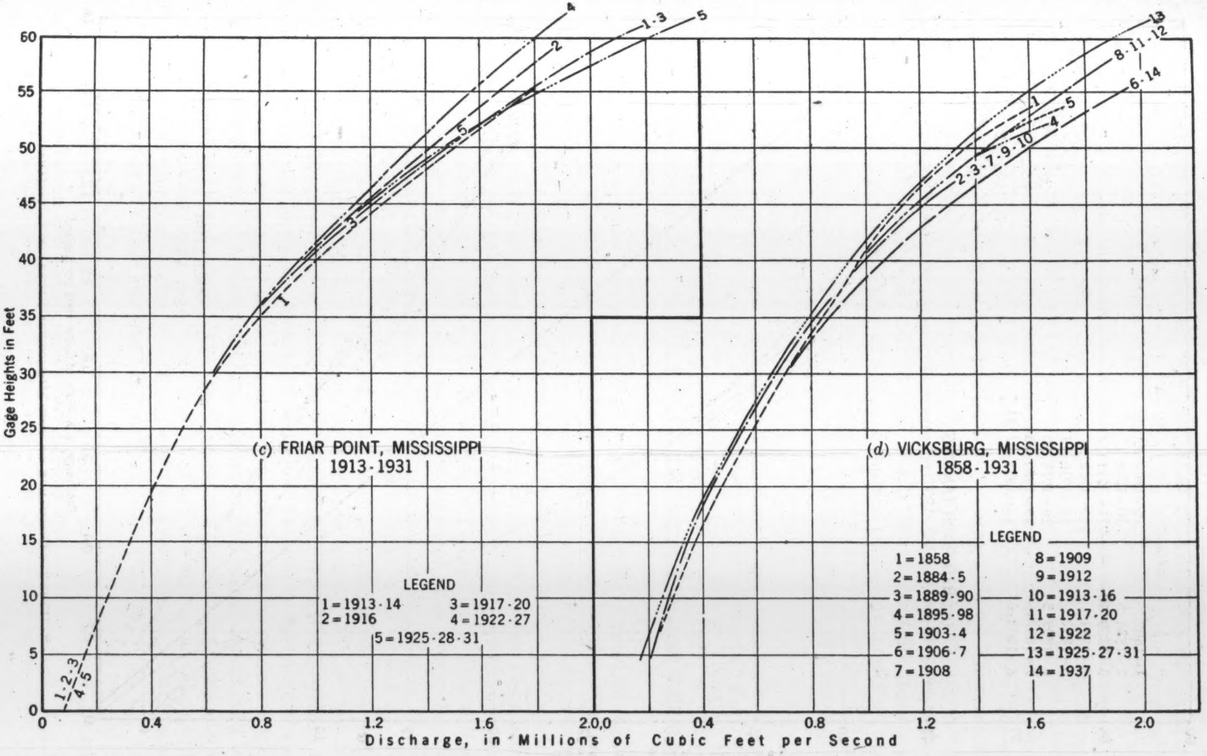

FIG. 2.—DISCHARGE OF THE MISSISSIPPI RIVER COMPILED FROM THE MISSISSIPPI RIVER COMMISSION AND THE U. S. CORPS OF ENGINEERS

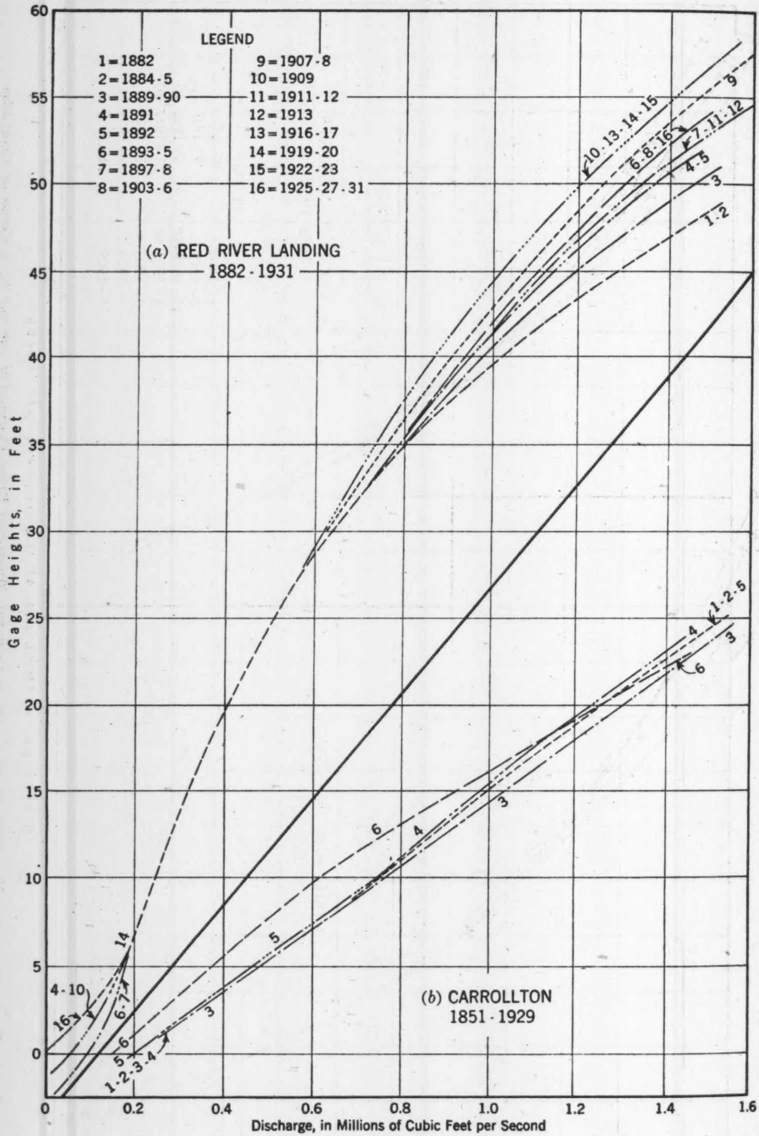

Fig. 3.—Discharge of the Mississippi River, in Louisiana

Table 7 lists the official, derived, and estimated quantities for the principal flood events to date, beginning with the 40-yr (or longer) maxima recorded at both Memphis, Tenn., and Vicksburg. This tabulation indicates that an addition of about 67% to the peak discharge at these two stations produced corresponding increases in maximum gage readings of 15.1 ft and 11.4 ft, respectively. Some undetermined part of these changes must be ascribed to reduced lateral flood-plain storage and total flood-channel section, due to confinement by levees. For Vicksburg, the rise of flood surface due to restrictions by levees was approximately 5 ft, according to data in Fig. 2(*d*). There is shown likewise some evidence of increased channel capacity during early periods, associated with removal of snags or other obstructions to navigation as well as to stream flow; and finally, in the 6-yr period, 1931 to 1937, the influence of cutoffs apparently restored the maximum discharge capacity, as proved by the low position of the rating curve No. 14. This is likewise in accordance with the findings of Brig.-Gen. Harley B. Ferguson,[17] M. Am. Soc. C. E., during his tour as President of the Mississippi River Commission.

Similarly, the writer found:[18]

> "For example, the gage-heights of 46.2 feet corresponding to a discharge of 1,520,000 cfs (Stages and discharge-observations, Lower Valley of the Mississippi River; Mississippi River Commission report, 1937) on March 30, 1891, was exceeded by 4-feet or more for equal discharges during the past 15 years or so."

In Fig. 4 are depicted the yearly, 5-yr, and 10-yr trends of precipitation at Marietta, and the Mississippi River runoff depths in inches over the watershed at Vicksburg, throughout the 123 years of record, including 1939. Apparently a fair correlation is obtained for 92 years, or 75% of the time on a yearly basis, slightly better on the 5-yr basis, and still more uniformly on the 10-yr basis. Likewise, the graphs of cumulative rainfall and runoff departures have several points in common, or nearly so, on the scales adopted; and either the parallelism of trends or their close association and interweaving of lines proves beyond reasonable challenge that this one rainfall station is more of an index to Mississippi River discharge at Vicksburg than would ordinarily be expected. No doubt a part of the explanation lies in the fact that Marietta is near the center of the most productive tributary basin, contributing nearly 50% of the discharge at Vicksburg. The addition of other outstanding station-records as they became available, up to a total of 10, was found to improve the correlation in some parts of the record; but the addition of widely distributed stations to a total of 50 seemed to disturb such correlation of the latter part of the record, as if too much weight was being accorded the areas of low runoff, such as the Great Plains.

For plotting the rainfall and runoff data to afford the most convenient comparison, it was found advisable to utilize a scale for precipitation depths either four or five times the scale adopted for runoff depths, as shown in Fig. 4. For the lower part of the drawing, dealing with cumulative departures, the datum or zero lines do not coincide. In the upper part of the same figure, the mean annual precipitation and runoff depths are slightly separated.

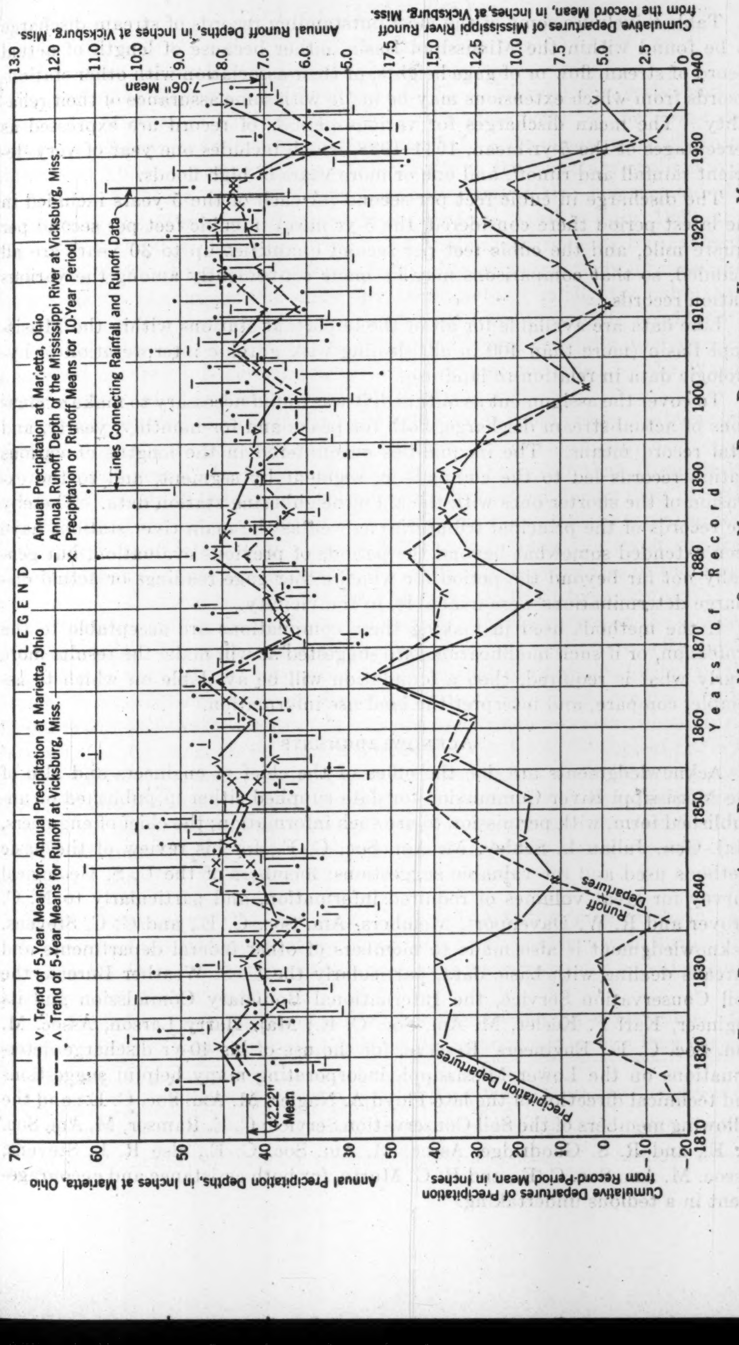

FIG. 4.—RELATIONS OF ANNUAL PRECIPITATION AT MARIETTA, OHIO, TO MISSISSIPPI RIVER DISCHARGE AT VICKSBURG, MISS.

Table 8 includes some of the most outstanding records of stream discharge to be found within the Mississippi Basin, either because of length of actual record of stream flow or of gage heights, or their association with other station-records from which extensions may be made with some assurance of their reliability. The mean discharges for various periods of record are expressed as percentages of the 5-yr mean, 1934–1938, which includes one year of very deficient rainfall and runoff, and one or more years of high floods.

The discharge in cubic feet per second for each of the 5 years included in the latest period there considered, the 5-yr mean in cubic feet per second per square mile, and the cubic feet per second quantities up to 30 years are all included, so that comparisons may be made conveniently among the various station records.

Like data are available for all of the important stations within the Mississippi Basin (more than 400 in all) dealing with graphic interpretation of hydrologic data in relation to land use.

To cover the assignment as outlined, it was found necessary to make evaluations of actual stream discharge, both for peaks and for monthly, yearly, and total record means. The inequalities encountered in the lengths of various station records led to the comparison, segment by segment, and to the extension of the shorter ones with the aid of neighboring station data. Thereby the records of the principal tributaries as well as the main river stations have been extended somewhat beyond the periods of previous evaluation, but generally not far beyond the period for which either gage readings or actual discharge determinations were available, in the vicinity.

If the methods used in making these compilations are acceptable to the profession, or if such modifications are suggested as will make the results more nearly what is required, then a foundation will be available on which to assemble, compare, and interpret the land use information.

ACKNOWLEDGMENTS

Acknowledgments are due the office of the chief of engineers and also of the Mississippi River Commission for data supplied either in published or unpublished form, with permission to use such information; the chief of engineers, Maj.-Gen. Julian L. Schley, M. Am. Soc. C. E., for his review of the basic methods used and for valuable suggestions; members of the U. S. Geological Survey for great volumes of required information, and particularly to N. C. Grover and R. W. Davenport, Members, Am. Soc. C. E., and G. C. Stevens. Acknowledgment is also made to members of other federal departments and bureaus dealing with basic data, particularly the U. S. Weather Bureau, the Soil Conservation Service, the International Boundary Commission and its engineer, Karl F. Keeler, M. Am. Soc. C. E.; Maj. Harry Larson, Assoc. M. Am. Soc. C. E., Engineers' Reserve, for the use of his 40-yr discharge determinations on the Lower Mississippi, incorporating many helpful suggestions and technical direction of the late Floyd A. Nagler, M. Am. Soc. C. E.; and the following members of the Soil Conservation Service: C. E. Ramser, M. Am. Soc. C. E., and R. S. Goodridge, Assoc. M. Am. Soc. C. E., also R. L. Stevens, Assoc. M. Am. Soc. C. E., and H. C. Murto, for both assistance and encouragement in a tedious undertaking.

DISCUSSION

Robert Follansbee,[19] M. Am. Soc. C. E.—Although the early contributions to Mississippi River hydrology were made chiefly by the Army engineers, the Navy made its contribution even before the classic work of Humphreys and Abbot. Acting under instructions from the Secretary of the Navy, Lt. Robert A. Marr, master of the Memphis Navy Yard, investigated the discharge of the Mississippi River at Memphis from April to July, 1849, and from March, 1850, to February, 1851. He made measurements by means of floats, and deduced the mean velocity from surface observations by means of floats sunk to various depths. The reduction factor was slightly more than 10%. He also obtained daily gage heights, and from these gage heights and the results of the discharge measurements he computed the daily discharge for the period covered. A description of this work was presented by the Washington Astronomical and Meteorological Observatory.[20]

The author refers to the earnest approaches made by the early contributors to Mississippi River hydrology toward the more rigorous standards developed during recent years. In that connection it may be noted that Humphreys and Abbot's study of the vertical-velocity curves obtained during their investigations indicated that the velocity at different depths varied as the abscissas of the parabola which had its x-axis parallel to and below the water surface. However, they did not pursue further the study of the properties of the parabolic curve. That was reserved for a British engineer, Maj. Allen Cunningham, who, during the 1870's, made 565 sets of vertical-velocity curves on the Ganges Canal in India. He concluded that, by considering the vertical-velocity curve as a common parabola, its properties indicated that the mean velocity equals $\frac{1}{2}$ (velocity at 0.211-depth + velocity at 0.789-depth).[21] These are practically the 0.2-depth and the 0.8-depth. It was not until 1906, however, when H. K. Barrows, M. Am. Soc. C. E., then a member of the U. S. Geological Survey, made a study of vertical-velocity curves and found that their form was that of a parabola, the mean ordinate of which was closely the average of the ordinates at the 0.2-depth and the 0.8-depth, that the procedure of measuring the velocity of these depths and taking the average as the mean velocity was adopted by the U. S. Geological Survey as its standard.

R. W. Davenport,[22] M. Am. Soc. C. E.—The author's research in the early records of the Mississippi River constitutes a valuable service in furnishing a "panoramic view" of the flow of this dominant waterway for a period of considerably more than a century.

The long-time compilations of runoff presented in the paper are subject to use in a variety of ways, not only for fixing the mean runoff over a long period of years but for studies of trends, and variation in magnitudes, for possible correlation with other factors. The author has included comparisons of deviations of runoff with those of rainfall. He also has in mind that the data may form a foundation on which to assemble, compare, and interpret land-use information.

It is particularly desirable in such uses of runoff data that the relative refinement of the data be known so that one may consider the extent, if any, to which evidence of relationships, apparent or sought for, may be influenced by fortuitous or systematic errors. It is not uncommon for such errors to obscure or to invalidate the significance of the evidence. It is desirable, as the author indicates, to suggest modifications that will make the results more nearly what is required for such uses. It is also very essential to know the inherent limitations of the results so that they may not be applied unwisely. If the data are satisfactorily free of such errors, the further question should be considered as to whether the significance of the factor investigated, such as land use, may be masked by other factors, particularly those of climatic variation.

The writer has been greatly impressed with the tremendous quantity of data concerning the history and behavior of the Mississippi River and feels quite humble in discussing a subject of which his knowledge encompasses comparatively little. The points raised herein are not intended to be in the way of criticisms, but more in the way of questions on which it is hoped the author may throw light.

The longest record developed is that of the Mississippi River at Natchez from 1817 to 1938, a period of 122 years, the results being shown in Tables 5 and 6. The technique used in the determination of the record in the earlier years may be learned by a perusal of *Professional Paper No. 13*,[23] which presents results for 33 out of the 42 years from 1818 to 1860. These records apparently were based on stages prior to 1848 solely at Natchez, and subsequently mostly at Carrollton and Donaldsonville, La. There seems to be very little information for appraising the accuracy of the basic stage records.

The stage-discharge relation for the Natchez station was determined from discharge measurements in January and February, 1858, at Natchez, and for the remainder of the year it was determined at Vicksburg and transferred to Natchez. In developing the relation a mean curve was apparently drawn through the loops described by the individual measurements of rising and falling stages. The inaccuracy involved in the determination of the discharge for a given day would tend to be compensative in computing the discharge for the year. The mean annual discharge was determined essentially by application of the twelve mean monthly stages of the year to the rating table, adding the results, and dividing by twelve.

The discharge determinations consisted of velocity measurements made by means of timing double floats, the most common form being a surface float of cork to which was attached a paint keg, the depth of submergence of which was fixed by a cord attached to the cork. The kegs were passed at all depths from the bottom to the top, but a uniform depth of 5 ft seems to have been adopted for general use. The mean velocities of the floats were determined for divisions 200 ft in width, and the products of the mean surface velocity and the areas of the cross sections for such divisions were computed and added for the entire cross section to give the "approximate discharge." Soundings were made in the vicinity of Natchez in January and in the vicinity of Vicksburg in February, September, and December during 1858, which apparently gave the basis for the areas of cross sections to be used in the discharge computations.

---

[23] "Report on the Physics and Hydraulics of the Mississippi River," by A. A. Humphreys and Henry L. Abbot, *Professional Paper No. 13*, Corps of Engrs., U. S. Army, 1876.

The "approximate discharge" was corrected by a ratio designed to adjust the float velocity to the mean velocity in the section and also to take account of the prevalent condition of the wind. Similarly, the discharges at Carrollton and Donaldsonville were computed from measurements made in 1851 and 1852.

This early river measurement technique, briefly summarized herein but described fully in *Professional Paper No. 13*,[23] was unquestionably the best afforded by the knowledge and facilities of the time and was conducted with supreme care. It may be compared with that used at the present time by the Geological Survey for the gaging station at Vicksburg:[24]

> "Discharge Measurements.—Discharge measurements are made from the downstream side of the highway section of the bridge. The highway section is on the upstream side of the bridge, and the railway section on the downstream side. The metering equipment is lowered through an opening between the floors of the highway and railway. The equipment is operated by means of a reel and boom mounted on a low-wheeled truck frame. The truck frame also carries a four-cylinder automobile engine which supplies power for operating the metering equipment and moving the truck from point to point along the bridge. Depth of water and position of meter are shown by a depth indicator attached to the reel. During medium and high stages the depth of water and velocity are such that the metering equipment is carried downstream and the indicated depth is too large. Conversion to true depth is effected by use of two correction tables, one of which gives the correction to slant length of supporting line above water surface, and the other gives the correction to curved length of line below water surface. The use of each table requires a measurement of the vertical angle in the supporting line above the water surface, and this measurement is accomplished by use of a protractor applied to the line just below the bridge floor. The corrections to indicated depth are lessened by the use of large sounding weights. The maximum sounding weight used at the Vicksburg station is 300 pounds.

> "Determination of Discharge.—Daily discharge determined by shifting-control method. Changes in stage-discharge relation determined by frequent measurements."

From the establishment of the Vicksburg gaging station in 1930 to the end of the water year 1941, 1,524 discharge measurements have been made at this station, generally two to three days apart, to record the vagaries of the flow of the river. Fig. 5 illustrates the plotting of discharge measurements in 1938 in excess of 700,000 cu ft per sec. The writer is unable to state how typical this period may have been. However, the plotted points suggest the complications involved in the determination of the stage-discharge relation for application to the stage records. Soundings are made for each discharge measurement and the cross sections thus determined indicate considerable variation during short periods. Comparisons of areas of cross sections for gage heights of 28 to 30 ft from soundings from 1933 to 1939 indicate an increase in area of about 10%. This increase may have been associated with the effects of cutoffs below Vicksburg. However, it illustrates another changing aspect of the behavior of the Mississippi River.

[24] *Water-Supply Paper No. 747*, U. S. Geological Survey, Washington, D. C., 1933, p. 16.

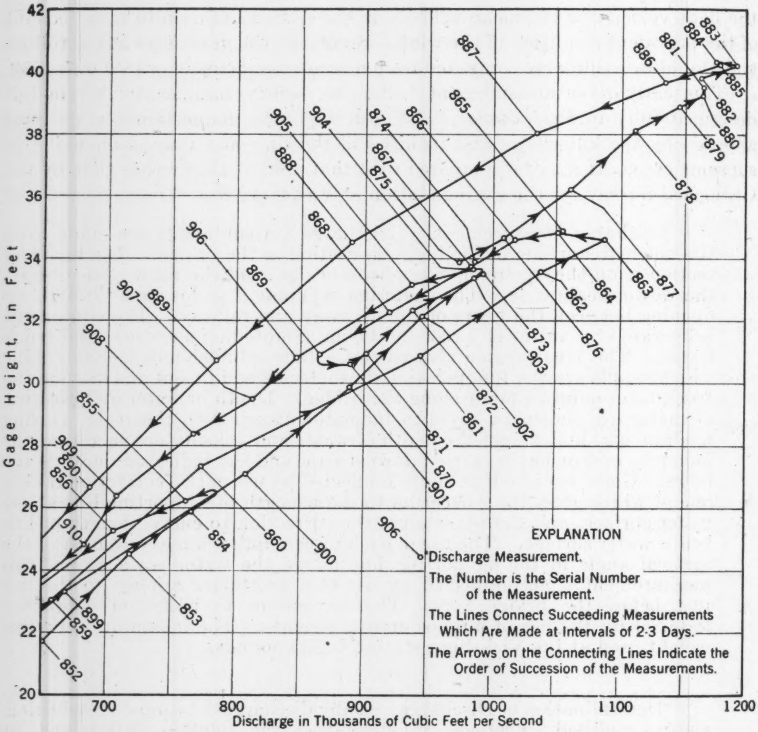

FIG. 5.—DISCHARGE MEASUREMENTS, MISSISSIPPI RIVER AT VICKSBURG, MISS., 1938, U. S. GEOLOGICAL SURVEY

The application of the stage-discharge relation as determined for Natchez in 1858 involves questions of reliability of stage records, the accuracy of the compensative adjustment by use of a mean curve drawn through rising and falling branches of the plotted measurements, uncertainty as to cross-sectional areas applicable at the time of a measurement, and other matters pertinent to a pioneer technique. Much more serious than these questions, however, are those pertinent to the application of the 1858 stage-discharge relation preceding the period in which the determining observations were made as far back as

1818. Illustrations in "The Improvement of the Lower Mississippi River for Flood Control and Navigation"[25] delineate pronounced progress in channel changes in the Mississippi River below Vicksburg and Natchez between 1820 and 1861 and also, apparently, in the construction of levees.

Fig. 2, which shows rating curves of the Mississippi River at Vicksburg from 1858 to 1937, indicates that in that period the mean rating curves that have been defined have varied within limits approximating ±5%. It is apparently not demonstrated, however, that changes influential on the Vicksburg-Natchez section of the river may not have been substantially more operative in the period 1817 to 1858 than in the later period.

The critical feature in respect to the use of the earlier records is the cloud of uncertainty resting over their reliability. The author recognizes this situation in his supposition that modifications may be suggested that will make the results more nearly what is required for the analysis of land-use information. It is notable that the Mississippi River Commission has not included such earlier records in its compilations of past records—for what reason the writer is not informed. In their present status, it is important to caution earnestly that in any applications of the records their inherent nature as respects accuracy be kept in mind.

Charles Senour,[26] M. Am. Soc. C. E.—A well-deserved tribute is paid, in this interesting paper, to the early observers of Mississippi River phenomena, whose painstaking care and understanding went far toward compensating for the shortcomings of their comparatively crude equipment.

Table 1 records annual discharges of the Mississippi River at Natchez for most of the period 1818 to 1859, as obtained from *Professional Paper No. 13.*[23] Captain Humphreys and Lieutenant Abbot measured discharges at Natchez in 1851 and 1858 by subsurface floats. A vertical curve of velocities for the station was prepared and the equation determined for converting velocity at 5-ft depth to mean velocity. From these measurements they developed a stage-discharge relationship curve, and, utilizing this in conjunction with monthly mean stages, deduced the mean annual discharges. Mr. Jarvis has supplemented the Humphreys and Abbot data with later observed or derived data and, in Tables 5 and 6, has extended Table 1 to 1939.

To compare actual measured discharges with those indicated by the stage-discharge curve, the writer plotted all observed discharges at Natchez or at stations between that point and Old River from 1851 to date, in terms of the gage used by Humphreys and Abbot. Fig. 6 shows the zone of extreme variations of those plottings, as compared with the rating curve. The discharges were found to fit the curve very well except for the stages below 15 ft. Of course, there is a fairly wide spread (about 140,000 cu ft per sec in the upper portion of the field) between rising stage and falling stage discharge for the same gage height, so that the mean curve, as a rule, would not give the true discharge for any particular date except (perhaps) at the crest of a rise; but in using it to develop an annual mean or total discharge such discrepancies would tend to compensate. At this particular station, the stage-discharge relationship appears to have been rather constant for the years in which discharge was measured. Measurements have been far from continuous, however. The range has never been considered a highly desirable one, because of very deep water and large boils which give rise to questions regarding the accuracy of both velocity measurements and soundings. Since 1884, measurement of either high water or low water has been made practically every year at both Vicksburg, Miss., and Arkansas City, Ark., and since 1927 the observations have covered a much longer period of each year. At Red River Landing the same process has been in use since 1881. At Natchez, however, following those of Humphreys and Abbot, no measurements were made until 1890–1892. Again there was a hiatus until 1927 and another between 1927 and 1934. In 1911–12–13 measurements were at Point Breeze, about 57 miles below Natchez. In 1928 a range was established at Tarbert Landing, just above Old River, and measurements have been made there annually since that date. Since 1934, annual measurements have also been made at Natchez. What changes the stage-discharge relationship may have undergone during the long periods for which there are no data, and what that relationship may have been between 1818 and the Humphreys and Abbot measurements, are not known. It is known, however that there were major adjustments in the form of Shreves Cutoff and Raccourci Cutoff in 1831 and 1848, respectively.

[25] "The Improvement of the Lower Mississippi River for Flood Control and Navigation," prepared by D. O. Elliott, under the direction of T. H. Jackson, U. S. Waterways Experiment Station, Vicksburg, Miss., Vol. III, May 1, 1932, Plates VI(f), VI(g), VI(h), and XXXII.

[26] Head Engr., Mississippi River Commission, Vicksburg, Miss.

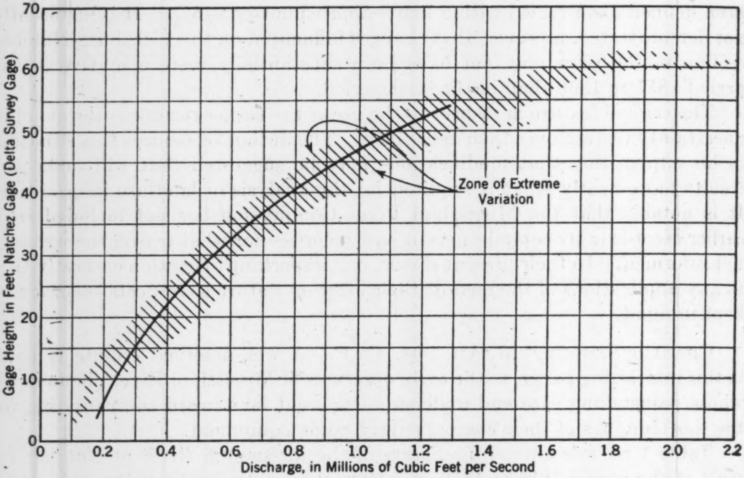

FIG. 6.—DISCHARGE OBSERVATIONS; MISSISSIPPI RIVER, AT NATCHEZ, MISS.

Constancy of stage-discharge relationship is by no means the rule on the lower river. The gradual growth of the levee system to a stature that really permitted confinement of flood flows to the channel, the gradual lengthening of river bends, and their subsequent elimination from time to time by cutoffs, natural or planned, together with numerous other phenomena of regimen, all have combined to produce a changing rather than a fixed relationship. At some stations (Arkansas City and Vicksburg, for example) the changes have been very pronounced, as is evidenced by the rating curves for various years submitted by Mr. Jarvis. Records of actual measurements show that at Vicksburg the stage required to pass a rising stage discharge of 1,000,000 cu ft per sec was about 40 ft in 1890, 38 ft in 1896, 40 ft in 1898, 37 ft in 1906, 40 ft in 1916, 42 ft in 1928, and 31 ft in 1940. Bankfull stage is 42 ft. The increment, in discharge per foot of stage, is about 50,000 cu ft per sec on this part of the curve. Deduction of past flows from present rating curves could introduce errors of a couple of hundred thousand cubic feet per second or more in many cases. During periods of Vicksburg observations the results at that point could be translated to Natchez, probably without very serious discrepancy, but this device is not available for the period anterior to Humphreys and Abbot. This is not intended as a condemnation of the methods employed by the author, who has used the data very ingeniously, indeed. Parenthetically it might be observed that at Vicksburg the 1937 rating curve presented by Mr. Jarvis lies about 100,000 cu ft per sec to the left of that developed by the Mississippi River Commission for the same year below the 35-ft stage. There is a closer agreement above that stage.

On the Mississippi River, the derivation of annual discharge by the use of monthly mean stages should yield fairly accurate figures, provided the rating curve reflects the true relationship between discharge and stage and provided no flow by-passes the station by reason of diversions through levee breaks. In extreme floods of earlier years there were numerous crevasses in the levees, and outflow through those in the west bank levees below the Arkansas River would not reenter the Mississippi above Natchez. The method of monthly mean stages was applied to the Vicksburg record for the years 1930 through 1936, using the appropriate rating curve in each case. Compared with the results obtained by adding together the daily discharges as actually measured from day to day or as scaled from loop curves connecting measurements two to several days apart, the mean annual discharge as developed from monthly mean stage was:

Year	Percentage higher or lower than the sum of daily discharges
1930	0.04% higher
1931	2.85% higher
1932	1.03% lower
1933	1.02% lower
1934	0.96% lower
1935	1.61% lower
1936	0.74% lower

In Table 3 Mr. Jarvis presents maximum stage and discharge at Carrollton (New Orleans) for each of the years 1811–1860. The Carrollton gage readings prior to 1847 were apparently deduced from readings on the Natchez gage. The relationship between gages on the lower Mississippi is not constant and the Mississippi River Commission has not as a rule included in its published pamphlets any stages other than actual gage readings or water marks connected to the gage by levels. Incidentally, crest stages at Carrollton as established by high-water marks and published by the Mississippi River Commission for the years 1832, 1840, and 1844 do not agree with those reported in Table 3. The discharges reported in Table 3 were taken from a Carrollton rating curve developed from discharge measurements at Red River Landing (just below Old River) in 1851 and at New Orleans in 1858. Fig. 7 shows this rating curve about which the writer had plotted all available discharge observations at Carrollton. The zone of extreme variation of these plottings is indicated by the cross-hatched area.

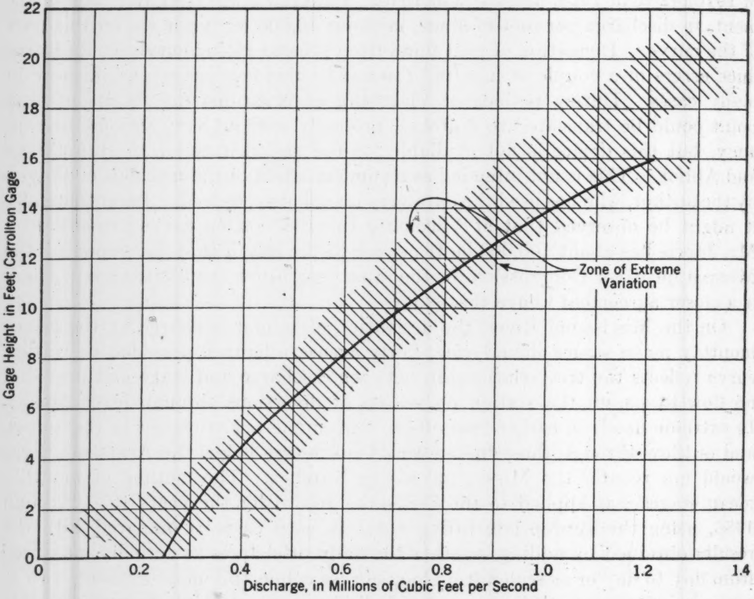

FIG. 7.—DISCHARGE OBSERVATIONS, MISSISSIPPI RIVER, AT CARROLLTON, LA. (1851–1941)

Some clarification of the data presented in Table 7 would be desirable. The table presents maximum gage heights and discharges at Memphis and Vicksburg for the period 1858 to 1937. The Memphis stage for June 23, 1858, should read (with reference to zero of present gage) 34.16 ft instead of 35.3 ft. The stages tabulated for Vicksburg from 1858 to 1931 relate to the U. S. Engineer gage, whereas those subsequent to 1931 apparently relate to the U. S. Weather Bureau bridge gage and are from 0.6 to 2.3 ft lower than the corresponding readings on the Engineer gage. Many of the discharges tabulated are unofficial or estimated quantities. Presumably they are estimated confined flows and so, in the cases of floods not completely confined, do not correspond to the observed gage heights tabulated opposite.

It is noted that for 1909, 1916, 1920, and 1928, estimated discharges are given for Vicksburg, whereas these floods were fully confined at that point and measured confined discharges are available. The discharge given for 1922 was measured after a crevasse had developed 93 miles below Vicksburg and two days after the crest had passed, and was probably influenced by the crevasse. The Vicksburg discharge given for 1927 (namely, 2,495,000 cu ft per sec) appears to be made up of the estimated confined inflow at Arkansas City plus the flow of the Yazoo River. The estimated confined flow at Vicksburg[27] is 2,278,000 cu ft per sec. The actual measured peak flow was 1,806,000 cu ft per sec on May 1, 1927, at a stage of 57.2 ft. The maximum stage was 58.4 ft on May 4, 1927.

The value (2,020,000 cu ft per sec) is the actual measured confined discharge past Memphis in 1937. It is not believed necessary to add the extra 500,000 cu ft per sec.

The data presented in Table 7 should be used with caution. The peak flows of the older great floods were seriously affected by crevasses both above and below the gaging points. The only common basis for comparison is that of confined flow, and it is extremely difficult in many cases to arrive at a satisfactory estimate of it.

In conclusion it might be well to comment on the reference to the blue clay in which the early and many later observers fancied the river bed to lie. Borings disclose that the bed is in sands and gravels. The clays generally exist in old abandoned channels of the river and in old marshes and appear to be the results of deposits of fines from the river itself.

John C. Hoyt,[28] **M. Am. Soc. C. E.**—The pioneer work in the collection of river flow by Humphreys and Abbot[2] and others on the Mississippi River indicated a fair recognition of the fundamental principles of the subject. The principles then recognized have stood the tests of later studies of the subject, and they have been the basis for the further development of the science of river hydrology.

Mr. Jarvis' paper brings together the results of much of the early work on the Mississippi River in a form that makes them readily available for further comparison and study. The comparison of records of river discharge taken at different times depends on three main factors: (1) The methods used in their collection; (2) the equipment and facilities available for collecting the records; and (3) the permanency of conditions along the streams which regulate the flow.

Although the methods of measurement are fundamentally the same, the equipment and facilities for making the measurements have been greatly modified and improved so that the accuracy in recent work has been greatly increased; for example, improvement in sounding equipment has added materially to the accuracy of records. Whereas some streams have fairly permanent channels which govern their regimen, many of the larger ones change and shift their channels to such an extent that measurements of discharge or stage made at one time are not comparable with others made at other times.

[27] "Basic Data, Mississippi River," *Annex No. 5*, H.R. Doc. No. 798, 71st Cong., 3d Session, 1931, p. 105.

[28] Cons. Hydr. Engr., U. S. Geological Survey, Washington, D. C.

In comparing records of different dates collected along the Mississippi River, the effect of the changes in conditions which affect the flow must be kept in mind, and there will always be an element of uncertainty which requires caution in their use. Although these comparisons may give a general idea of the conditions, they will always be open to question and should be used with great caution.

GEORGE O. GUESMER,[29] ASSOC. M. AM. SOC. C. E.—The source and accuracy of original data which are the basis for a study of any subject determine the value of the conclusions reached. Mr. Jarvis' diligence in "digging out" information buried for years in the records of various offices in the Mississippi River Valley has given him an excellent background.

The writer had an opportunity to observe Mr. Jarvis gathering information used in the preparation of this paper. The comprehensiveness of his research was evident not only from the continuous testing and correlation of each new "lead" but also from the new derivations made in the light of basic data assembled in the course of related studies and research projects. Every effort was made to be certain that each item was thoroughly examined and worthy of consideration. Thus, the paper is based on information carefully weighed by the author during selection at the original source.

H. T. CORY,[30] M. AM. SOC. C. E.—It is most unfortunate that a wholly unjustifiable adoration of the Golden Calf Precision has blinded so surprisingly many to the solid substantiality of what early investigators and constructors did and knew. That Mr. Jarvis should have realized the Humphrey and Abbott early Mississippi records merited thoroughgoing examination by modern critical methods and should have discovered that the endeavor was very much worth while—is reassuring. It is to be hoped that his example will be followed, and followed frequently.

Sometimes the rejection of old-time "crudely observed" data approaches the tragic. An example coming within the writer's personal experience is a case in point. In 1912 he had occasion to meet an old gentleman then 94 years old, who had a remarkably keen memory, supplemented by scattered notes preserved in old notebooks, which were not diaries in any sense.

Among the many impressive and stirring events discussed, the most striking was his being taken, when a youth, by an uncle on a trip to Cincinnati, Ohio. At this time there must have been a notable drought for he vividly recalled having seen the steamboats resting crosswise on the Ohio River bed with the only water in the river running under and not touching the boat bottom.

The writer naturally grilled the old gentleman thoroughly, and was convinced he had described exactly what he had seen at Cincinnati on that trip. Absurd as it may seem to those who have not, more than once, been dumbfounded by the "incredibility" of high and of low extremes of stream discharge and yet lived to see such extremes reached if not exceeded, the writer is convinced that about 1835 the discharge of the Ohio River at Cincinnati fell to, relatively speaking, zero. Several times the incident has been brought to the attention of the federal water resources officials during the thirty years since 1913 but apparently to no purpose. Such "stream gaging" is certainly very crude, and yet —.

---

[29] Engr., U. S. Engr. Office, St. Paul, Minn.

[30] Superv. Engr., Reconstruction Finance Corp., Los Angeles, Calif.

After all, there is no doubt that the best way to bring proper attention to such cases of "rejected data" is to follow Mr. Jarvis' example and to present carefully prepared papers to the Society for its information and discussion. The present paper may well be taken as a model.

C. S. JARVIS,[31] M. AM. SOC. C. E.—Mr. Davenport has contributed an interesting, thought-provoking discussion, which discloses specifically why the most earnest attempts at evaluation and interpretation of early discharge records are under such a handicap, in the judgment of those best equipped to carry the project forward or to encourage and guide other investigators. Against all the implications that such a task cannot be accomplished with even a fair degree of reliability, only one answer is ventured:

> Every independent, unbiased, logical approach toward the evaluation and coordination of those early records pays a tangible dividend, either by establishing, confirming, or revising usable estimates and approximations. We are surely nearer to the truth now than we were before any sustained attempts were made at evaluation. Further investigations and revisions are invited. Thus far, many confirmations have resulted from various approaches.

Acting in conformity with basic legislative and administrative authority, Humphreys and Abbot collected available pertinent information concerning flood heights, crevasses, levee construction, and dimensions on the Mississippi River,[32] "and well authenticated changes in the banks of the river, etc. * * *. In each set of cross-sections, the velocity of the current was measured—in some instances, with great elaboration." In view of such items of record, exception must be taken to the concept expressed by Mr. Davenport, implying that practically the sole authority for discharge and cross-sectional data, as well as for the rating curve for the early years of record, was the 1858 series of discharge and gage readings at Vicksburg, Miss., and Natchez, Miss. As opposed to such a theory, note the comparison of methods used for float measurements in 1851 and 1858 and, also, the unsatisfactory tests of Saxton's current meter.[33] Some of the following references prove that fragmentary data were collected prior to 1850 (some as early as 1838), and that the results were available for incorporation in the final report.

Among the many references that establish the broad scope of investigations included in the Humphreys and Abbot report, the following have been selected:[34]

> "The corresponding velocity, taken from a table constructed for the purpose, was considered to be the mean velocity of the division—absolute for the observations of 1851, and relative for those of 1858. For the shore divisions, unless the floats happened to be well distributed through them,

[32] "Report on the Physics and Hydraulics of the Mississippi River," by A. A. Humphreys and Henry L. Abbot, *Professional Paper No. 13*, Corps of Engrs., U. S. Army, 1876, p. 2.

[33] "Report on the Physics and Hydraulics of the Mississippi River," by A. A. Humphreys and Henry L. Abbot, *Professional Paper No. 13*, Corps of Engrs., U. S. Army, 1876, p. 234.

[34] *Ibid.*, p. 235.

the mean velocity was assumed to be eight-tenths of that at the outer edge, a rule deduced from a subdivision and study of the velocity, when thoroughly measured in these divisions [200 ft apart]."

Also in this report, included in George G. Meade's letter,[35] is a brief description of his extensive observations relating to current velocities, directions, and vertical distributions in and around the delta channels during the year 1838; and there is a reference[36] to the 90-ft cord used for connecting the surface float with the submerged float. The location[37] of the maximum velocity in a depth of 100 ft is given as 30 ft from the surface—a fair approach to what is acceptable today.

Furthermore, there are numerous references to records and measurements conducted by Lt. Robert A. Marr, U. S. Navy, Prof. C. G. Forshey, M. Am. Soc. C. E., and Charles Ellet, Jr., during years earlier than 1850 (for example, Lieutenant Marr's record of daily rainfall, gage heights, temperature, and river discharge at Memphis, Tenn., together with weekly evaporation, April 1 to July 15, 1848,[38] river data, March 1, 1850, to March 1, 1851, and related activities[39]).

After describing the discharge and other measurements on the Lower Mississippi River from February, 1851, to February, 1852, and from December, 1857, to December, 1858,[40] Humphreys and Abbot declared, "Besides these continuous series, many measurements of width, depth, area of cross-section, discharge, etc., were made both upon the Mississippi and upon its tributaries and bayous from the Ohio to the Gulf." It seems reasonable to assume that all such data underlay the discharge determinations for the 33 years listed in Table 1. These values are of acceptable quality, as proved repeatedly by various approaches described hereafter.

Even though the scope of the statement concerning other measurements outside the continuous series may apply mainly to the one decade covering the Humphreys and Abbot assignment, the aforementioned and associated references indicate that it is applicable in some degree for the years preceding 1850. Thus, the persistent attempts to evaluate the tributary, main channel, and crevasse discharges, and to correlate these quantities at successive stations from Columbus, Ky., to Carrollton (New Orleans), La.,[41] unmistakably indicate the avidity with which the authors incorporated basic data and extended their use within practicable limits. Unquestionably, some of those segments of gage-height hydrographs for the Natchez, Vicksburg, and New Carthage, Miss., stations (the latter lying between the first two),[42] for 33 years, 1818 to 1860, were associated with series of discharge determinations, by means of floats; either natural—driftwood and uprooted trees—or artificial—weighted rods or multiple floats—as noted in various pages of the text. Otherwise, the separate determinations of discharge by Lieutenant Marr, Professor Forshey, and Mr. Ellet cannot be accounted for nor accredited reasonably.

The rating curve for the earliest biennium of record at Carrollton, 1851 and 1852, depended on more than 100 separate gagings, of which 21 were definitely dated on the chart. There can be no reasonable doubt that the earlier fragmentary or detached data were incorporated in some manner to make the rating curves more nearly representative of conditions during earlier years. Otherwise, it would be difficult to account for the close agreement in the last two columns of Table 1, showing 33-yr means of 614,000 cu ft per sec and 617,000 cu ft per sec, a difference less than 0.5%, even though the means for the last 10 years of the same tabulation differed by nearly 2.0%. It would be gratifying, indeed, if one could be assured that stream-discharge determinations under the most up-to-date, standard practice could stay within such close limits, or that the separate records of earlier periods were within limits five times as great.

Fig. 5 is of unusual interest because it follows the general form of patterns set in earlier years by the Mississippi River gagings at Natchez, Vicksburg, and Warrenton, Miss., beginning in 1858; at Columbus, in 1857; and at Carrollton, as early as 1851. For the last-named station, well-defined segments of rating curves are available for twenty-one separate years or groups of years between 1851 and 1929. They all lie within the limits of those curves selected for inclusion in Fig. 3 for Carrollton and are numbered chronologically from the earliest to curve 6, the rating curve for 1929. With few exceptions, the successive patterns at all gaging stations on the Lower Mississippi River show deviations of more nearly ± 5% as against ± 10% in the positions of rating curves near El. 34 (Fig. 5). The most outstanding exceptions are afforded by the records of river gagings at Columbus, for the years 1857–1858, and 1881–1882, showing somewhat greater variations than ± 10%. This pronounced variability persists in diminishing degree at the same station to include the year 1937, according to the writer's interpretation of official data, published mainly by the Mississippi River Commission. This analysis seems to provide a tentative answer to the query, for which Mr. Davenport admitted he had none, as to how nearly typical was the variation in plotted gagings for the year 1938 at Vicksburg. Fig. 5 typifies the shifting of rating curves for the more erratic periods, but not for the maximum variability.

Recent official records for the Lower Mississippi River stations disclose consistent relationships generally, but occasional departures of 5% or more for gagings by different agencies (or even by the same agency) with the river surface elevation practically constant.

1. Would it seem inconsistent to ascribe some portion, possibly approaching one half of the aforementioned 20% variation for the gagings in Fig. 5, to both the personal equation of the operators and the inherent defects or erratic movements of current-meter vanes due to suspended silt and fine granular material or other debris encountered in all such rivers, but never in the standard rating flumes of laboratories?

2. With all the refinements now applied to the measurements of depths at intervals along the cross section, what uncertainties still persist because the

heavy sounding weight settles into the mud or silt of the stream bed or because it encounters either a ridge or a valley?

3. Is the square foot, or portion thereof, occupied by the current meter for the purpose of determining velocity of flow actually representative of the thousands or tens of thousands of such elementary areas within the cross section for which it serves as a sample?

In view of such unsolved problems as well as the shifting of currents and bars within a cross section and in view of the pulsations of waves or unpredictable movements of eddies in the course of turbulent flow (with all other uncertainties inherent in stream gaging on deep alluvium even where the best practical standards prevail), it seems noteworthy that such consistent relationships have been developed and maintained between river stage and discharge.

No less amazing are the results achieved normally in connection with the early gagings of the Mississippi River system without the conveniences afforded by fixed bridges (being dependent upon floating equipment and shore installations or observations, as well as extra labor and ingenuity) to accomplish the difficult assignments under pioneer conditions. Surely, some compensations must have accrued from the direct measurements of stream velocities by weighted rods, multiple floats, or uprooted trees. This procedure integrated and averaged the movement within much larger samples of cross-sectional area, and furthermore avoided the inherent approximations of rating tables for current meters and the recognized uncertainties involved in their practical use. There is some reassurance in the observation that velocities are determined by the use of floats to this day, when circumstances warrant, either for flood crest or for routine gagings; and results are duly published along with those obtained by the use of current meters, with symbols to indicate whether one or two meters, double floats, rods, or surface floats were employed. Many current-meter gagings have had the advantage of float measurements to test the action of the meter vanes, even though these experiments were not necessarily included in the published reports.

Mr. Follansbee has contributed some very interesting historical notes relating to the development of the art and science of stream gaging.

Mr. Hoyt has written his impressions, based on a much broader experience than comes to most. With deep gratitude the writer acknowledges the encouragement accorded by Mr. Hoyt, particularly in the projects for evaluation and comparison of flood data pertaining to foreign rivers, such as the Nile, as well as to American rivers, especially those with the longer records.

Mr. Senour has contributed a number of important items that would be difficult to obtain outside the central office of the Mississippi River Commission. Fig. 6 provides an authoritative answer to many queries that have been directed toward the writer, as to the stability of stage-discharge relationships at the lower stations. Because the 4,900 sq miles of intervening drainage area between Vicksburg and Natchez represent only 0.43% of the total, although the proportionate runoff was more nearly 1%, the data at each of these stations have served at times for both, with the single percentage differential taken into account wherever circumstances warranted. Inclusion of the complete data for 1937, which were not available when Fig. 2 was prepared, provides an added rating curve, as described by Mr. Senour, to the right of curve 6 for Vicksburg. For 1941 the rating curve is still farther to the right, according to the U. S. Geological Survey, presumably measuring the increase of channel capacity resulting from cutoffs. The Natchez gage readings were about 5 ft higher for equal discharges, traceable to a lower datum with respect to hydraulic slopes for successive stages.

The three crest stages for Carrollton for the years 1832, 1840, and 1844, to which Mr. Senour takes exception, were merely transcribed along with associated data in Table 3 from *Professional Paper No. 13.*[43] If the several curves of Fig. 3 pertaining to Carrollton gagings are plotted or superimposed on Fig. 7, these rating curves will be found to cover approximately one half of the shaded area along the central strip. This shows that the variations among single observations are nearly double the range occupied by rating curves. When it is realized how nearly the extreme variations recorded in Fig. 5 equal those in Figs. 6 and 7 (the latter two covering 90 years instead of the single year 1938), the factors of the personal equation of operators and the practical limitations on the accuracy of current-meter gagings seem to demand consideration.

In response to Mr. Senour's request for clarification of data presented in Table 7, it should be noted that the writer aimed to record the progressively increasing concentrations of flood water associated with peak discharge and aggravated soil wastage, including both the confined channel flow and the well-defined storage or lateral floodway capacities then in use. Examples of this concept were reported in 1929 by C. W. Kutz, M. Am. Soc. C. E.,[44] as 2,662,000 cu ft per sec at the latitude of Arkansas City, Ark., in April, 1927, or 2,350,000 cu ft per sec near Old River, La. At the same time, General Kutz (then Colonel) dealt with possible or probable maximum floods at Cairo, Ill., ranging from 2,250,000 cu ft per sec to 2,400,000 cu ft per sec. According to George R. Clemens,[45] M. Am. Soc. C. E.:

> "Thus the Mississippi River met the first thrust of the 1937 flood. Cairo was the only dry city in the Ohio basin. The New Madrid floodway functioned essentially as planned, and protected not only Cairo but the entire St. Francis basin from a flood that most certainly would have overtopped the levees as they stood in 1927. At the crest, about 2,000,000 cu ft per sec passed Cairo, and about 500,000 cu ft per sec was carried in the floodway."

The writer's concept was that the same 500,000 cu ft per sec could be regarded as in temporary storage or detention between Cairo and Memphis, Tenn. The plan sponsored by the Chief of Engineers to[46] "provide for a flood which without reservoir control would reach 2,600,000 cubic feet per second in the Mississippi between Cairo and the Arkansas" was based on both a knowledge and a thorough understanding of the data including the 1937 flood rise, the well-organized defense of the Cairo levees, the relief afforded by the access to the New Madrid floodway, and the potentialities of future floods.

[43] "Report on the Physics and Hydraulics of the Mississippi River," by A. A. Humphreys and Henry L. Abbot, *Professional Paper No. 13*, Corps of Engrs., U. S. Army, 1876, p. 443.

[44] "The Work of the Mississippi River Commission," by C. W. Kutz, *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 707.

[45] "The Mississippi Meets the 1937 Flood," by George R. Clemens, *Civil Engineering*, June, 1937, p. 381.

[46] "Comprehensive Flood-Control Plan for Ohio and Lower Mississippi Rivers," *Committee Document No. 1*, House Committee on Flood Control, 75th Cong., 1st Session, April 6, 1937, p. 6, paragraph 20.

Another reference which seems to support the concept of total discharge from both confined channel and floodway or lateral storage is to be found in an article by Maj. Raymond G. Moses:[47] "At the crest, of course, the Arkansas-White backwater area was still taking water but the flows from those two streams were sufficient to increase the flow in the main river to about 2,150,000 cfs at the crest at Arkansas City * * *."

The tabulated discharges for the years 1909, 1916, 1920, and 1928 are weighted means of either official or semi-authoritative data. Official quantities including the latest revisions should be preferable.

Mr. Guesmer not only observed some of the initial investigations of Mississippi River discharge data, but also participated to the extent of locating some of the most valuable folios and summaries of unpublished hydrologic data, of which the writer had no previous knowledge. It seemed logical to deal first with the headwaters and then with the successive tributaries and main river stations. The procedure thus developed was found to be very satisfactory and capable of deriving successive discharge quantities generally within 5%, and often within 2%, as illustrated in Table 9 for the Tennessee River at Savannah, Tenn.

TABLE 9.—DISCHARGES, IN CUBIC FEET PER SECOND, FOR THE DESIGNATED YEARS OR OTHER PERIODS

Description	Latest 10 yr	5 yr 1934–1938	1937–1938	1936–1937	1935–1936	1934–1935	1933–1934
271

Departures (numerical)	254	263	−1,500 748[a]	−828	290	−824	417
Departures (%)	0.5	0.5	1.5	−1.5	0.5	−1.6	1.0
272							
Observed	54,909	52,438	51,210	58,140	59,030	54,040	39,780

[a] Initial filling for storage in reservoir was 1,091,000 acre-ft, representing an inflow of 1,500 cu ft per sec for one year.

The initial reckoning disclosed an unusual departure of nearly 4.5% for the water year 1937–1938 until it was discovered that the initial filling of the reservoir accounted for the withdrawal of 1,500 cu ft per sec from the stream flow. In the same manner, it was quite a simple problem to derive the yearly and periodic mean discharges for Cincinnati, Ohio. For this purpose, the observed discharges of the Ohio River at Huntington, W. Va., were correlated with records of the gaged tributaries and estimated yields for the ungaged areas. The latter were either equal to or somewhat less than the observed discharge per square mile of the gaged tributaries. For any of the intermediate stations on the Mississippi River and its major tributaries, or even the minor branches, this procedure seemed to render acceptable values.

Various tests showed that the ungaged portions of valley floors ordinarily yield somewhat less than do equal areas in steeper and more elevated regions.

---

[47] "High Water in the Lower Mississippi," by Raymond G. Moses, *The Military Engineer*, May-June, 1937, p. 167.

Furthermore, it is generally known that the larger tributaries head on the higher ground; therefore it is customary to estimate the yield per square mile of ungaged areas, including minor tributaries, as 80% or 90% of the unit yield for the adjacent gaged tributaries. Observed and derived discharges for 56 stations selected from among the 400 or more available are listed in Table 8.

The progressive summations, comparisons, samplings, and adjustments which led to these results for all important stations within the Mississippi River basin involved the following principal phases:

1. Assembly of outstanding and representative precipitation records;
2. Interpolations from neighboring stations to fill all gaps;
3. Comparisons of monthly or yearly means for the group of stations with the total record means to obtain excess and deficient depths for successive months or years;
4. Computations of temperature departures from normal in the same manner, for one or more representative stations;
5. Computations of runoff departures from record mean at the selected lower river station (record-mean annual runoff depth minus successive yearly depths);
6. Comparison of rainfall and runoff departures in the light of temperature departures from normal;
7. Investigation of particular storm patterns in all cases where rainfall and runoff departures are greatly at variance or of opposite signs;
8. Derivation of discharge at the lower river station from summations of tributary discharges and estimates of ungaged areas based thereon;
9. Interpretation of hydrographs in the light of all previously assembled data and their established relationships; and
10. Checking the arrays of data by the use of weighting factors, used in multiplying the different tributary discharges in order to build up the approximation to the lower station discharge, year by year, month by month, or day by day, if time factors, valley storage, and flood routing are all taken into account.

Weighting Factors.—The concept and use of weighting factors may be explained best by a practical example. In the quest for suitable samples of tributary flow that may be used as an index of lower station discharge, the essential criteria for tributary records include not only their length, continuity, and quality, but also their degree of correlation with discharge at the lower station. The Gasconade River at Rich Fountain, Mo., is outstanding for such correlation; the Kanawha River at Kanawha Falls, W. Va., has a record of outstanding length and reliability. Their respective drainage areas of 3,180 sq miles and 8,367 sq miles, totaling 11,547 sq miles, represent nearly 1% of the 1,144,500 sq miles drained above Vicksburg, and the average yield is 2.667% of the total. Evidently, an approximation to the annual discharge at Vicksburg is afforded by taking $\frac{100}{2.667} = 37.5$ times the recorded discharges at Rich Fountain and Kanawha Falls, according to the normal procedure for the "sampling method."[48] The weighting-factor development came in response to the query, "Would it be more satisfactory to accord different weights to the tributary drainages, calling for a greater factor for the Gasconade River and a lesser one for the Kanawha River, or vice versa?" Adopting the water years 1939 and 1940 for the observation or test period, the simultaneous equations become: For 1938–1939,

$$2{,}787\,x + 10{,}090\,y = 572{,}600 \ldots\ldots (1)$$

and for 1939–1940,

$$1{,}611\,x + 10{,}940\,y = 332{,}500 \ldots\ldots (2)$$

$$\frac{2{,}787}{1{,}611} \times \text{Eq. } 2 = 2{,}787\,x + 18{,}926\,y = 575{,}219 \ldots\ldots (3)$$

$$\text{Eq. } 3 - \text{Eq. } 1 = 8{,}836\,y = 2{,}619 \ldots\ldots (4)$$

$$y = 0.296401 \ldots\ldots (5)$$

Substituting the value of y (Eq. 5) in both Eq. 1 and Eq. 3—$2{,}787\,x = 569{,}609$; and $x = 204.3807$.

This disparity in weighting factors results in almost complete dependence on the smaller tributary, outstanding indicator of Vicksburg discharge.

Use of the foregoing weighting factors for the Gasconade River and Kanawha River annual discharges for the 20-yr period, 1921 to 1940, resulted in a maximum departure of + 46.3%, with a mean absolute of ± 21.0%, as recorded for Item 17, Table 10. According to data under Item 91 (Table 10*B*), the substitution of discharge data from the Greenbrier branch of the Kanawha River, draining only 1,357 sq miles, with the Gasconade area, representing only 0.4% of that at Vicksburg, resulted in new weighting factors of 204.9578 and 25.756673, respectively. Under a 20-yr test, 1922 to 1941, these factors proved to be more satisfactory than the first pair, as the maximum and mean-absolute departures were reduced to − 42.4% and 15.1%, respectively, for the Mississippi and Atchafalaya rivers. However, Item 22 indicates what may be attained by such tests with 87.2% gaged, resulting in reduced percentages of + 10.2% and 3.6% over a 22-yr checking period. Such percentages approach so nearly the attainable accuracies in river gaging on alluvial formations that they seem to attest the consistency and reliability of the basic data underlying those derivations or estimates; furthermore, they may constitute a proof or indorsement of the derivation and testing method employed. Similarly, in Item 7 (departures of − 23.9% and 9.6% for 65 years), in Item 32 (departures of + 20.4% and 7.9% for 52 years), and in Item 67 (departures of + 18.2% and 5.7% for 52 years), the fairly close agreement between derived and observed discharge data extends beyond the range of mere coincidence.

The fact that some other series of weighting factors, similarly derived, bring more discordant results would seem to indicate that either the test years or the individual tributary discharges were less representative. For example, the aforementioned Kanawha River discharges showed a larger quantity for the lean year (1939–1940) than for the average year (1938–1939) at Vicksburg, and, therefore, the resulting weighting factor is small, and shifts most of the burden to the smaller Gasconade River.

[48] "Estimating Annual Yield from Ungaged Drainage-Basins and Effect of Land-Use Treatment on Surface-Runoff," by C. S. Jarvis and H. C. Murto, *Transactions*, Am. Geophysical Union, 1941, pp. 875–893.

Least Squares Solutions.—Items 102 to 107 in Table 10*B* and Items 45 and 46 in Table 10 were solved by the method of least squares. The obvious advantage of this approach is that the observation period may be extended beyond the number of years that corresponds to the number of unknowns. Actually, the practical application of the simplest algebraic approach was found to accomplish the same results. For example, a 20-yr period may be divided into four groups of 5 years each and used effectively for the determination of four unknown weighting factors, as shown in Table 10, Item 54.

After a searching investigation and numerous tests, the most significant of which are summarized in Tables 10, it was found that the method of least squares (with all the extra labor that the procedure involves, particularly in the formation of normal equations) yields either identical results that accrue from the simplest algebraic approach with simultaneous equations, or a generally comparable series of factors. Occasionally, the results from the least squares procedure show up to advantage, but more often the advantage was with the simpler approach. Wherever the constant value is included among the unknowns, the summations of normal equations direct the solution toward the series of factors that will satisfy the arithmetic means of the observation equation coefficients and, therefore, will not likely satisfy any one of them separately.

The main objective of Tables 10 is to illustrate some of the methods used both in extending the records and also in checking the values thus derived as to their consistency, one with another, in the light of such fragmentary or local records and such other information or authoritative interpretations as were available.

These and associated tests have disclosed errors in some of the published basic data, and have indicated the required correction. For example, the mean annual discharge of the Missouri River at Hermann, Mo., for the calendar year 1925, once published as the equivalent of 76,130 cu ft per sec, was found to be more nearly 50,000 cu ft per sec by various tests similar or related to those in Tables 10, and also by reference to the established rainfall-runoff relationships as applied to that year at the stations involved. Likewise, the numerous maximum departure percentages recorded in Col. 25 indicate that the lower station discharges for the year 1931 are probably deficient and should be increased by at least 10%, revising data of that year prior to July, when the present station was established.

The method of least squares brings identical results with those from the simplest algebraic method whenever the unknowns, the tributary stations, and years or other time units in the test period are all equal in number. Values derived in connection with a constant term, which automatically extends the test period by one year, represent mean discharges for the entire test period, and therefore should not normally satisfy any of the individual observation equations.

The aforementioned observations are not intended to disparage the use of the least squares procedure in its proper field, for it has done much to facilitate

[j] Mean discharges at the lower river station weighting factors above listed.

scientific analysis and research. However, the criteria for the application of that method are violated mostly in the hydrologic field, especially as to a large number of observations made with equal care and skill, all yielding small deviations from the mean. Items 45 and 46 in Table 10 represent the best of the least squares tests, with maximum departures of some 29% in a 52-yr checking period, in contrast with 13.7% for Item 47.

[n] For additional values in Cols. 4 to 9, see Tables 10 and 10*B*. [o] Including the latest revisions of both observed

According to authoritative analyses of probabilities,[49] the standard error of the standard deviation should be as large as the deviation itself whenever the number, *n*, of observation equations and unknowns is equal to 3; and for *n* equals 10, the odds are 3 to 2 that the calculated probable error is within 20% of the correct value; furthermore, the odds are 30 to 1 that the error is within 50%.

and derived in estimated data. [p] All ten stations. [q] Slide-rule calculations only.

The investigations underlying this paper have demonstrated that the suitability or representative character of the observation equations far outweighs the influence of number. Some arrays of data covering only 2 or 3 years have outdone other arrays of 6 or 7 years, or such numbers as 10, 15, or 20. One test of 25 years in groups of five each, yielding a set of five 5-yr means, was found to have imposed so many conditions that the weighting

year; in these columns, unmarked years are drought years except 1939 (an average year). [f] With Atchafalaya, to the gaging stations in the main headings. [h] Computed by least squares, and normal equations solved. discharges to obtain the ratios, or uniform weighting factors above listed. [r] For further information regarding factors were unwieldy and thus useless for the purpose intended, with constants exceeding 6,400,000 cu ft per sec and 8,200,000 cu ft per sec, respectively, for Vicksburg and Angola-Simmesport, Items 53, Table 10.

The only basis thus far disclosed for satisfying the fundamental criterion (that the sum of the squares of deviations shall be a minimum) involves, either directly or indirectly, some multiple of the arithmetic means of the respective coefficients appearing in the observation equations. Comparable results may be had by including the means of all or of a part of the test period, along with any desired number of seemingly representative yearly data, as illustrated by Items 92 and 93, Table 10*B*. Somewhere within the twilight zones of mathematical probability, fantastic legends have grown up, attributing almost magic powers to the least squares procedure, when simpler methods achieve either identical or comparable results, as shown by many items associated with those in Tables 10.

Mr. Cory's comment regarding an extremely low stage of the Ohio River at Cincinnati calls forth a simple test, based on official records as shown in Table 11.[50]

TABLE 11.—RAINFALL DEPTHS IN INCHES AT MARIETTA, OHIO, FOR CRITICAL MONTHS, 1833–1836

Month	1833	1834	1835	1836	Means, 1817–1930
July	6.84	5.08	2.58	3.16	4.63
August	0.25	1.33	6.54	3.16	3.85
September	3.30	0.67	2.75	2.08	3.03
October	3.17	3.75	4.80	2.50	2.91
Yearly depth	40.37	34.66	42.46	36.76	42.25

A casual examination of the foregoing data in the light of the close correlation of Marietta rainfall with runoff as far down the river system as Vicksburg justifies the conclusion that the time of minimum discharge of the Ohio River at Cincinnati was September, 1834, in the second successive month of subnormal rainfall, and in a year of drought following a slightly sub-normal year. As to the actual discharge, it might have been anything from 3,000 to 5,000 cu ft per sec inasmuch as such minima have been observed from Huntington to Louisville, Ky., within recent years. A channel cross section of about 70 ft by 10 ft might have been spanned by those early steamboats. As mean velocities of 4 to 7 ft per sec would account for such minimum discharges, there is no occasion to challenge the veteran's boyhood memories; they correspond with the probable conditions of flow.

It is worthy of note that the same year that marked the establishment of methodical rainfall records at Marietta, Ohio, and of Mississippi River gage heights at Natchez, saw the election of the eminent scientist, Pierre Laplace, to the presidency of the French Academy. Napoleon's complaint upon the occasion of his dismissing Laplace from the office of Minister of the Interior had to do with "administration on the basis of differential calculus," or "of infinitesimals," according to other translations.

---

[50] *Bulletin W*, U. S. Weather Bureau, 1930, and later data.

The accustomed praise accorded the Humphreys and Abbot hydrologic data and findings, coupled with the practical disregard and discounting to which they have been subjected entirely too long, may well have its origin in the application of calculus or the Laplace and Gaussian theories of probabilities to data in the rough, where practical application of experience and the simplest mathematical approach would have served better. Intensive studies of those early data pertaining to the Mississippi River system would have been richly repaid if no other result had been achieved than disclosing the fruitless hours devoted to building up the usual normal equations, preparatory to their solution as simultaneous equations, when the basic observation equations are capable of yielding either identical, fairly comparable, or more satisfactory values of the respective unknowns, as described herein. This comment in no wise circumscribes the use of calculus, probabilities, least squares, or other preferred methods within their proper sphere, but is aimed against ill-advised or improper application of such procedure, either inside or outside their respective provinces. The gross errors inherent in either the instrumentation, the sampling, the observations in the field, or their interpretations in the office, or the summation of these defects, would seem to disqualify the ordinary run-of-the-mill hydrologic data for analysis by the method of least squares, where large numbers of small deviations constitute the most suitable arrays. Nevertheless, the normal alternation of plus and minus errors seems to effect such compensations so as to render the best attainable values of rainfall and runoff; and these have consistently withstood the most practical tests as to their suitability and reliability for the purposes intended—evaluation, conservation, and utilization of water resources.

CLASSIFICATION OF IRRIGABLE LANDS

By W. W. Johnston,[1] Esq.

With Discussion by Messrs. R. Earl Storie, Walter W. Weir, W. L. Powers, and W. W. Johnston.

Synopsis

Land classification as conducted in the Bureau of Reclamation is on the basis of utility for irrigation farming. Three main types are made which are similar in main essentials but differ in detail and refinement. The principal function of all these is to eliminate from the area to be irrigated (arable land) lands which do not have sufficient productive capacity to support a farm family at a reasonable level of living and permit the payment of construction assessments. The "arable" lands are further divided into classes and subclasses on the basis of productive value under irrigation.

Introduction

The term "Land Classification," as used by various agencies in recent years, has been applied to a variety of land maps that differ widely both in purpose and detail. In some cases it means the separation of broad areas on the basis of "type of use," such as industrial areas, recreational areas, and the like, as distinguished from lands that are primarily suited to agricultural uses. More commonly, lands are classified on the basis of their adaptation to different types of agricultural use, such as forest areas, grazing lands, and lands suited to different types of crop production.

Land classification, as conducted in the Bureau of Reclamation and discussed in this paper, is on the basis of utility for irrigation farming, and much of its strength lies in this singleness of purpose. The most important phase of this work is the separation of lands suitable for irrigation (termed "arable") from inferior lands not suited to irrigation development (non-arable). To be suitable for irrigation, land must not only be located under the ditch and of a surface relief even enough to be irrigated, but it also must have sufficient productive capacity to support a family at a reasonable level of living and to permit the payment of irrigation assessments. The arable lands are divided fur-

ther into two or three classes on the basis of productive value and the ability to meet irrigation assessments, class 1 representing the highest class arable land and class 3 the lowest. The non-arable lands are placed in class 6 except where special classes are mapped that include portions of the "non-arable" land as here defined, on which surplus waters may be used to advantage on a yearly rental basis for some limited use, such as irrigating pasture. Frequently, subsequent economic investigations will indicate that when intermingled with better land, so that a farm unit will include only a small percentage of this type, such portions of the acreage in the special classes properly may be supplied with a regular water right and be subject to regular irrigation assessments. In reclassification of old projects, class 5, a suspended class, is frequently used to include lands that are temporarily unproductive, pending the construction of needed drainage or other action which will restore productivity.

A study of its history shows that since its inception there has always been some kind of land classification practiced by the Bureau of Reclamation. The earlier land studies were generally not extended to great detail, and the importance of soil conditions was not recognized to the same extent as at present. Little was known about arid soils and their response to irrigation, and in the earlier years there was a tendency on the part of practically every one interested in irrigation to believe that all land below the irrigation ditch was susceptible of producing satisfactory crops if only the water were delivered to it. Experience has demonstrated, however, that good soil is as important as sufficient water, and few irrigation developments have stabilized with as much land under irrigation as was originally contemplated.

The Modern System of Land Classification

The modern system of classifying irrigable lands began with the passage of the so-called "Fact-Finders Act" of December 9, 1924, wherein provision was made for the classification of project lands on the basis of ability to meet construction charges. Experience and study during the intervening years have resulted in the development of methods and standards now in use. Although land classification is used for essentially economic purposes, it is necessary to base the distinction between classes on physical conditions, of which soil, topographic, and drainage characteristics are of primary importance. Climate is likewise an important factor in gaging the productive capacity of an area, but generally it is reasonably uniform within the boundaries of a single project and therefore does not enter into the division of land into classes.

Soil characteristics vary so greatly from place to place that it is difficult to establish a set of soil conditions that are uniformly applicable as a guide in determining irrigability. In the central valleys of California, for instance, medium to light-textured sandy loams and loams of recent alluvial deposition, such as river deposits adjoining the Sacramento River and soils formed from alluvial fan deposits of the smaller streams, are the more successfully irrigated, whereas the older alluvial soils have developed hardpans and in many cases have been leached too extensively to be highly productive or to respond well to irrigation. In eastern Montana, on the other hand, the soils of mature development, which have become well weathered and have developed definite profile characteristics, are usually the most successful irrigated lands; and here the soils of recent alluvial deposition are likely to be either heavy intractable clays that have been formed from materials washed in from "raw" shale hills, or sandy soils derived from sandstone alluvium that has been little altered and is of limited fertility.

Certain soil characteristics are uniformly necessary, however. To be satisfactory for irrigation development, the soil must have a reasonably high water-holding capacity; it must be readily penetrable by water and still have a slow enough infiltration rate so that it can be irrigated without excessive percolation losses; it must be free from "black alkali" or a sodium-saturated condition; and it must be either nonsaline or of a type from which the moderate amounts of saline salts that it may contain can be leached readily. Also, the soil must be sufficiently deep to allow necessary root development and permit soil drainage. Arid and semi-arid soils that meet these requirements are practically always well supplied with mineral plant nutrients. The quantity of nitrogen is generally deficient, but this element is readily maintained by the production of leguminous crops that are the backbone of irrigation agriculture.

Topographic considerations are of two main types: First, the degree of slope; and second, the character of the surface relief—whether it is smooth or uneven. Likewise, the characteristics of the soil in respect to erosion, permeability to water, and susceptibility to "subbing" or lateral movement of water between furrows must be considered, and the methods of irrigation that have proved to be adapted to the region cannot be ignored in fixing the topographic limits for the different classes. In the broad smooth valleys of Arizona and California, the use of large heads of water and flooding in borders, checks, or basins has proved to be the most practicable method of irrigation for all except row crops and possibly orchards. In central Washington, on the other hand, the corrugation method of irrigation has proved to be well adapted to soil and topographic conditions and is used for all types of crops, almost to the exclusion of other methods. Irrigation heads are small and, particularly on the steeper slopes, the use of flumes and irrigation pipe, which permit accurate control of water to the corrugation, is common practice. Under the latter conditions slopes of from 10% to 15% are used successfully under irrigation and are classified as arable where soil conditions are favorable. Under conditions prevailing in the former localities, on the other hand, the permissible limit of slope is generally less than 10%.

Lands of moderate gradient, but of uneven surface, are considered both from the standpoint of the cost of necessary leveling and the probable effect of surface soil removal on fertility. In general, deep soils of recent alluvial deposition can be graded heavily with only temporary curtailment of productive capacity, but older soils that have developed zones of lime accumulation in the subsoil, and also soils of limited depth to rock or gravel, cannot be heavily graded without seriously decreasing crop production in spots where heavy cuts have been made.

Some future drainage requirements are to be anticipated on all new projects, and it is difficult, and in many cases impossible, to determine in advance where seepage development will take place. In land classification, therefore, eliminations from the irrigable area because of adverse drainage conditions are limited to areas without surface outlets and to narrow draws and valleys where early seepage development is to be anticipated and drainage costs will obviously be in excess of benefits. Lands are placed in class 2 or 3 because of adverse drainage conditions where more than average hazards of seepage development exist but conditions are favorable for artificial drainage construction at reasonable cost.

METHODS

In order to achieve the objectives of land classification, as previously discussed, and to assure uniform work where a number of classifiers are employed, it has been found necessary to establish certain physical standards or specifications for each class. This must be done for each project studied, although standards used in different parts of the West include certain similarities, and those applying to two areas having similar soils, climate, and irrigation practices will be correspondingly similar. In so far as conditions can be duplicated, standards are based on actual performance of similar lands under irrigation, and to this end it is customary, when establishing classification standards for an area of new land, to study carefully the results that are being obtained under similar soil and topographic conditions in near-by developed areas.

For instance, in starting the classification of Columbia Basin project lands, it was important to know which sandy soils of the area were suitable for irrigation development. This problem was studied on three near-by irrigation districts where sandy texture has been the principal limiting factor in the success of the area under irrigation. Soils were examined on farms that have been farmed profitably under irrigation for a long period of years, on others that have been less successful, and on farms that have gone out of cultivation after a few years' trial. The history of these farms was obtained from well-informed local people, the record of water use was secured, and soil samples were taken for mechanical analyses. The information obtained, considered in the light of the amounts of irrigation water that can be supplied economically, made it possible to fix the standard of soil texture for each class on the basis of demonstrated experience. The standards with respect to topography, stoniness, depth to rock or gravel, and other factors were determined in the same way, although it was necessary to consider irrigated lands in the Yakima and Kittitas valleys, in addition to projects immediately adjoining the Columbia River, in order to duplicate all of the principal soil and topographic conditions encountered on the Columbia Basin project.

The methods followed in making a land classification vary somewhat, depending on the detail required in the particular study. In all cases, however, the boundaries between classes are drawn on the maps in the field after careful examination of all physical conditions, including subsoil examinations. The reason for placing land in a lower class than "1" is indicated by placing an appropriate letter after the classification number. The letter "S" indicates a soil deficiency; "R" loose rock in the plow zone; "T" a topographic deficiency; and "D" a deficiency in drainage characteristics. Two or more letters are used when more than one factor is involved. Thus, the classification as 2ST indicates that the land is inferior to class 1 in both soil and topographic characteristics, whereas an area marked 2T is equal to class 1 in soil, drainage, and freedom from loose rock in the plow zone, but it is either too rough in surface or too steep in slope to be first class. The boundaries between lands placed in the same class for different reasons are delineated on the land-classification maps, as well as the boundaries between classes. In the ordinary procedure, only the acreage in each class as a whole is measured and reported. The maps include the necessary data, however, to permit the measurement of areas in the several subclasses as well.

Where detailed topographic maps or good aerial photographs are available for use as base maps, it is unnecessary to survey the actual boundaries because with such maps a competent man can sketch the boundaries between classes with no greater error than his judgment in determining where the class boundary should be. Where base maps of this kind are not available, it is necessary to use a plane table. Sufficient test pits or auger borings are made to explore subsoil conditions carefully, these being ordinarily extended to depths of 5 ft. The minimum number for detailed studies is one for each 40 acres; for semi-detailed classification, one for each 160 acres; and enough in reconnaissance studies to meet the less exacting requirements of that kind of study. Alkali determinations of pertinent soils samples are made where the need is indicated, and in some of the larger and more detailed studies field laboratories are maintained where mechanical analyses, percolation studies, and other soil tests can be made.

Types

In recent years the Bureau of Reclamation has attempted to standardize on three main types of land classification that are similar in the main essentials but differ in the detail and degree of accuracy attained. These are "Reconnaissance Land Classification," "Semi-Detailed Land Classification," and "Detailed Land Classification." It has been possible to standardize quite definitely in the case of the last two types, but the degree of accuracy attained in reconnaissance classifications has varied somewhat from one area to another, depending on the particular requirements of the investigation.

Reconnaissance Land Classification

The more general type of reconnaissance is usually made on maps having a scale of 2,000 ft to the inch or on aerial photographs of whatever scale available. This type is applicable to the study of large areas where it is desired to secure general information and to determine the location and extent of areas that are sufficiently promising to warrant more detailed investigations. An example is found in studies made in southwestern Wyoming in connection with the Colorado River investigations. Inspection showed this area to be made up largely of extremely shallow soil but to include also bodies of land of variable extent made up of better soil Consequently, it was decided to make a general reconnaissance land classification for the primary purpose of locating areas of sufficient promise to warrant more detailed study. In the absence of better base maps, township sheets with horizontal scales of 2,000 ft to the inch were made up from township data, and section corners were located and flagged on the exterior boundaries of each township. With these corners for initial control and a plane table for use in maintaining orientation and location, the general boundaries of class 1 and class 2 areas were mapped in each township, this work requiring an average of four days per township for two men. Arable areas having sufficient size to warrant further consideration, as indicated in the reconnaissance, were then covered by a semi-detailed land classification, this being the type that was followed more generally in these investigations. The results were satisfactory and the cost was a fraction of the amount which would have been required had the entire area been covered in the usual detail.

An example of a more accurate reconnaissance is the investigation the Bureau of Reclamation is making in the Sacramento Valley. This work, which eventually will cover several million acres, is for the purpose of obtaining an inventory of lands that may be irrigated from the Shasta reservoir and from storage which may be developed on tributary streams. Since the complete consummation of plans to be developed as a result of the investigations will stretch far into the future, the present requirement is for information on the location of lands of different capabilities and an estimate of acreage that is reliable for good-sized blocks but not necessarily applicable to a single farm or individual 40-acre tract. It is planned that a more detailed land classification will be made of any project resulting from these and other preliminary investigations before starting construction.

In this study, standards in respect to soil conditions are defined in terms of soil types as mapped in the county soil surveys, but all of the area is examined and the features of the classification are delineated on aerial photographs in the field. Where recent soil surveys are available, little additional work is necessary for the better soil types except to map topographic features and give due consideration to alkali. For inferior soil types, however, where only the more favorable phases are suitable for irrigation development, it is necessary to put down a reasonable number of soil pits and to give careful consideration to soil changes. This has been found to be true with all soil types in areas not covered by recent soil surveys.

The good valley lands that are suited to a wide variety of crops are included in classes 1 and 2. Class 1 includes the better lands which have deep, well-drained soils that are free from harmful quantities of alkaline or saline salts and are of favorable topography. Class 2 includes areas which are still "good farm lands" but are distinctly lower in productive capacity than class 1 because of some limitation such as heavy texture, limited soil depth, moderate salinity, or somewhat unfavorable topography. Class 3 is a "special" class made up of lands having restricted utility for irrigation farming. Class 3a includes the deeper and more productive phases of the "hardpan lands," and class 3b comprises the heavy clays, which have proved suitable for growing rice or for irrigated pasture but are not suited to a wide variety of crops. Portions of the rolling foothills that have irrigation possibilities are likewise in "special" classes, being designated as H-1 or H-2, the first representing the best and the second representing the less desirable of the hill lands that are found to be suitable in some capacity for irrigation.

Class 1 and class 2 lands include those which are capable of continued production and which will give a fair return to the operator, thus permitting the payment of substantial irrigation assessments. Lands in the "special" classes are types that have been proved by experience to be capable of some production under irrigation; but their development as irrigated land is more hazardous from the standpoint of the man who may settle on them and also the agency that must collect the construction costs. Areas found to be unsuited for irrigation, even in the limited capacity of the special classes, are classed as non-arable (class 6).

SEMI-DETAILED LAND CLASSIFICATION

The semi-detailed land classification (sometimes called detailed reconnaissance) is generally made on maps having a scale of 1,000 ft = 1 in., and is the type most usually followed in areas under investigation for development as individual irrigation projects. Ordinarily, only two classes of arable land (class 1 and class 2) and one class of non-arable land (class 6) are mapped, but special classes are sometimes included when the requirement is indicated. This type is very similar to the "Detailed Land Classification" except that, as the name implies, it is not carried to the same degree of refinement. With this limitation, the discussion of the latter type that follows in later paragraphs will apply to the semi-detailed type, and a thorough description is omitted from this section in the interest of brevity. A set of classification standards, which was used in the investigation of one project (Kendrick project, Wyoming), follows:

SEMI-DETAILED LAND CLASSIFICATION

Class 1, Arable.—
- Soil.—
  - Depth.—Four feet or more to shale or hard sandstone, 2 ft or more to gravel or loose rock.
  - Texture.—Fine sandy loam to silt loam and not seriously compacted.
  - Alkali.—Free from more than slight indication of neutral salts (white alkali); free of indication of black alkali either present or prospective.
- Topography.—
  - Smooth slopes of 5% or less with reasonably good-sized areas sloping in the same plane.
- Drainage Conditions.—
  - Soil and topographic conditions such that seepage would not be expected to develop soon and artificial drainage would be feasible at moderate cost.

Class 2, Arable.—(Areas placed in class 2 on account of deficiencies in either soil, topography, or drainage with the following minimum standards):
- Soil.—
  - Depth.—Three feet or more to shale, hard sandstone, or impervious clay; $1\frac{1}{2}$ ft or more to gravel or loose rock.
  - Texture.—Sandy loam to clay loam—some compaction permitted.
  - Alkali.—Slight to moderate indication of white alkali but not enough to prevent crop growth; free of indication of black alkali.

Topography.—

Smooth slopes between 5% and 10%, or rougher slopes that may be less than 5% in general gradient.

Drainage Conditions.—

Soil and topographic conditions such that seepage may be expected to develop rather quickly, but with reclamation by artificial drainage at moderate cost appearing feasible.

Class 6, Non-Arable.—(Areas placed in non-arable class because of failure to meet the minimum requirements for class 2 in either soil, topography, or drainage, or because of combinations of such deficiencies, including the following):

Soil.—

Depth.—Shallow soils usually overlying shale.

Texture and Alkali.—Compact clay soils that are generally somewhat alkaline and are only slightly permeable to water; excessively sandy soils that are generally more or less blown up into dunes and depressions.

Topography.—

Areas with rough topography that could be leveled and irrigated only at excessive expense and areas with general slopes greater than 10%.

Drainage Conditions.—

Areas to be classed as non-arable on account of drainage alone only in the case of stream bottoms, where it is obvious that the cost of artificial drainage will be excessive, and in depressed areas without outlets, although adverse drainage conditions as a contributing factor along with adverse soil conditions will result in further exclusions.

DETAILED LAND CLASSIFICATION

In detailed land classification the arable land is typically separated into three classes:

(1) Class 1 includes lands of relatively high utility for irrigation farming and suited to a wide range of crops.

(2) Lands in class 2 are suitable for irrigation farming but are less desirable than those in class 1 either because they will produce less or will be more expensive to farm under irrigation. They may have a lower water-holding capacity, as indicated by light texture or limited soil depth; they may be only slowly permeable to water because of clay layers or slightly penetrable hardpan in the subsoil; or they may be more expensive to irrigate because of steeper slopes, or more expensive to level because of uneven topography. Also, they may be restricted in soil depth, moderately saline, or have less favorable drainage characteristics than the class 1 lands.

(3) Class 3 is made up of land that is likewise suitable for irrigation development but is of restricted utility because of more extreme deficiency in one or more respects. Land placed in this class because of relatively steep slopes, but with first-class soil, may be very desirable for fruit production because of favorable air drainage and can be safely irrigated if a permanent cover crop is

maintained between the trees to prevent washing. On the other hand, class 3 land that is so classed because of inferior soil will be restricted to a smaller percentage of row crops in the rotation or, if of limited depth to impenetrable materials, may need to be kept in crops that shade the ground in order to limit saline accumulations. Class 3, therefore, includes lands on which the hazards of farming and also of collecting construction assessments are more acute than in the case of the higher classes.

The land classification of the Columbia Basin project in Washington, which was completed in the summer of 1941, is a good example of the "Detailed Land Classification." The order of land studies on this project included: First, the retracement of land lines; second, topographic surveys, in which maps were prepared having a contour interval of 2 ft and a horizontal scale of 400 ft to the inch; third, the land classification; and fourth, land appraisal. The results of each phase of the investigation were utilized fully in each successive phase. The topographic maps were used as base maps for the land classification, section sheets being prepared showing the various features of the previous surveys, with spaces provided for recording the results of soil profile examinations, analytical data, and notes. The physical standards that were developed on the basis of actual experience, as described in an earlier paragraph, are listed in Table 1. Although these standards were set up as a general guide, they were adhered to closely, except in cases where the peculiar combination of conditions required slight deviation. The limitations of soil depth, and the like, represent minimum requirements for the class, the average being considerably better than these minimum limits. For example, although the permissible minimum limit of 12 in. of loam above gravel or coarse sand was permitted for class 3, this minimum depth was approached in this class only in the case of small-sized spots in areas of larger size where the average depth was considerably greater, and where the topography was such that little or no leveling of the more shallow phases would be required. Lands classed as nonarable because of limited depth, on the other hand, will include many small-sized bodies of land that will exceed this minimum permissible depth for class 3. In other words, it is impossible to set up a set of classification standards that will cover all combinations of conditions encountered, and the individual land classifier was expected to use his judgment in following the "standards," to the end that class 1 would include the land of highest productive capacity with no specific limitations in utility; class 2 also would include good average arable land with a wide range of utility; and class 3, although of more restricted capability, still would be land that could be utilized successfully under irrigation if handled with reasonable care.

Table 2 contains a hypothetical map which, with Fig. 1, illustrates the principal types of soil and topographic conditions encountered on the Columbia Basin project and the manner in which they were handled in the land classification. Although this example is hypothetical in the sense that no single square mile exists on the project which is the counterpart of this map, it was made up by combining parts of several maps and therefore represents actual field conditions. No attempt has been made to have the acreage in the different

TABLE 1.—LAND CLASSIFICATION STANDARDS.—COLUMBIA BASIN PROJECT

Land characteristics	Class 1—Arable	Class 2—Arable	Class 3—Arable	Class 6—Non-Arable
(a) SOILS				Includes lands which do not meet the minimum requirements for Class 3. Also small areas of arable land lying within larger bodies of non-arable land when these would obviously not make usable fields. Arable areas which are isolated for irrigation by gravity (high) or those where the feasibility of making water delivery is questionable will be classified in the regular way and the matter of eliminating arable land because of cost of serving with irrigation water will be left for future determination.
Texture	Sandy loam to friable clay loam.	May be loamy sand if underlain by finer textured soil.	Loamy sand to friable clay.	
Depth:				
To gravel, sand or cobble	30 in. plus.	20 in. plus.[a]	12 in. plus.[a]	
To solid rock or impervious hardpan	48 in. plus.	36 in. plus.	36 in. plus, where flat or hummocky; 24 in. on smooth slopes.	
To caliche hardpan (slightly penetrable)	30 in. with 48 in. penetrable.	24 in. with 36 in. penetrable.	16 in. with 24–36 in. penetrable.	
To penetrable lime zone	18 in. with 48 in. penetrable.	14 in. with 36 in. penetrable.	8 in. with 24–36 in. penetrable.	
Alkali:				
Black alkali	pH under 9.0 in surface 3 ft; may have higher pH in subsoil if highly calcareous and total salts are low.	pH under 9.0 in surface 2 ft; may have higher pH below 2 ft if highly calcareous and total salts are low.	pH under 9.0 in surface 12 in.; may have higher pH below 12 in. if highly calcareous and total salts are low.	
Total salts	0.2 of 1% or less.	0.30 of 1% or less.	0.5 of 1% or less.	
Rock	None in the plow zone of a size that will interfere with cultivation.	Only scattering loose rock large enough to interfere with cultivation.	Not more than are generally cleared for cultivation.	
(b) TOPOGRAPHY				
Slopes	Up to 5% if reasonably large sized bodies slope in the same plane.	Up to 10% if reasonably large sized bodies slope in the same plane.	Up to 15% if slopes are very favorable.	
Surface	Smooth enough that leveling can be accomplished almost entirely with a float.	Moderate grading may be required.	May require heavy grading in spots but not more than has been general on similar developed projects.	
(c) DRAINAGE				
Soil and topography	Soil and topographic conditions such that no specific drainage requirement is to be anticipated.	Soil and topographic conditions such that drainage will probably be required but with reclamation by artificial means appearing feasible at reasonable cost.	Narrow valleys, etc., where drainage will probably be required. Also areas requiring surface outlets where these can be provided at reasonable cost.	

[a] At the minimum depths the soil should be sandy loam or heavier. Loamy sands underlain by coarse sand or gravel should be 20 to 30 in. deep (depending on the percentage of silt and clay) to qualify for class 3. Although areas may be placed in a lower class than "1" for any of the reasons listed above, they will generally be placed in the next lower class if decidedly inferior in two or more respects. The reasons for placing areas in a lower class than "1" should be indicated by placing the letters "S," "T," or "D" after the classification number, depending on whether the deficiency is in "soil," "topography," or "drainage." The boundary between the different classes should be delineated with a solid line and the boundary between areas placed in the same class for different reasons should be a broken line.

Fig. 1.—Hypothetical Profiles, Illustrating Classes and Sub-Classes for Principal Soil and Topographic Conditions of Project (See Table 2)

classes on this map proportional to the project areas, the extent of the more inferior types being relatively large on the hypothetical map in order that the maximum number of different conditions encountered in the land classification might be illustrated.

It will be noted that the results of twenty-four soil-profile examinations are recorded in Fig. 1. Conventional symbols, as illustrated in the upper left-hand corner, are used to indicate the soil texture and nature of materials encountered in the 5-ft profile examined. The location of each profile in Fig. 1 is indicated on the map of Table 2 by the number of the profile in a circle located on the map at a point corresponding to the place where the profile examination was made in the field. At twenty-eight other locations the soil depth to various materials is indicated directly on the map as, for instance, in the south center of the NE¼NW¼ where the small "square" appears, representing the location of a place where the depth was indicated as 35 in. to gravel. At such locations less detailed soil-profile examinations are made than at the regularly numbered profiles. These extra examinations are necessary in many cases in order to delineate properly the boundaries between classes.

It will be noted that in the northwest part of the section the land is class 1. Profiles 4 and 5 and the two "spot holes" near the center of the northwest quarter section (Fig. 1) show that this is a deep soil of medium texture, and the topography, although perhaps not ideal, is very good for irrigation purposes. Also, there is no indication of future drainage troubles. In the vicinity of profile 6, the classification is marked "2T," which indicates that, although the soil is good enough for class 1, the land has been placed in class 2 because the slope is somewhat steeper and the direction of fall is not uniform. The strip of land below profile 6, marked "6T," is in excess of 15% in general gradient and is being classified as non-arable on this account, in spite of the fact that the soil is of high quality. The classification of the more moderate slope below is "3T" and where the slope is still more favorable it changes to "2T." Farther south, in the W½ of the SW¼, the topography and drainage conditions are sufficiently favorable for classification as class 1, but there are soil deficiencies, as indicated by the letter "S" following the classification numbers. The classification in the NW¼SW¼ is class 3 and class 6 because of limited depth of soil above caliche (a slightly penetrable calcareous hardpan). The land in class 6 is too shallow for safe utility as irrigated land, and the land in class 3 is deep enough to be arable but has distinct limitations because of shallow soil depth.

Crossing the shallow "draw" and divide, in the S½ of the SW¼, a low terrace is encountered that is underlain by clear sand and gravel. This is classed as "2S" because of the limited depth of good soil above this loose material, which condition is indicated by profiles 17 and 24, Fig. 1. The areas to the east marked class 3R and class 6R, respectively, are made up of soils as desirable as the 2S area except for the presence of cobble and boulders in the plow zone, which has resulted in the least seriously affected part being classed as arable (class 3) and the remainder, where the boulders are too large and too thick to be removed economically to permit cultivation, being classed as non-arable (class 6). The narrow strip of "2SR" was so classed both because of limited soil depth above gravel and because of some boulders in the plow zone which will need to be removed to permit cultivation. An area of very fine soil and excellent topography occurs in the southeastern part of the section, which is in class 1.

Another set of conditions is encountered in the N½ of the NE¼. The class 6S area in the eastern part has topography that would permit irrigation, but this land is classed as non-arable because the soil is a loose sand. The area just to the south, which is marked "3ST," is in the lowest arable class for both "soil" and "topographic" reasons, the soil being sand and loamy sand, with a sandy loam subsoil, and the surface being rough enough to require a rather large amount of leveling. The topography in this area differs from that in the "3T" area, previously described, by having a rough surface of moderate gradient, whereas the first area was smooth but steep. The area of class 3S to the west differs from the class 2 land which it joins on the south only in being of more limited depth above gravel and sand. The rather steep slope marked "6ST" is non-arable both because of shallow soil and unfavorable topography.

The area immediately to the west of the last-described land illustrates the classification of three types of drainage conditions. This entire area meets the soil specifications for class 2. It is anticipated, however, that seepage will develop after the adjoining higher lands are placed under irrigation, which will be more serious in the class 6 and class 3 areas. It certainly would not be economical to build a drainage ditch unless it is necessary for the class 2 area, and in this case it undoubtedly would not be deep enough to protect the class 6 land, and the class 3 land probably would have to be used for pasture. The area of class 2S at the N½ corner has a slope that would facilitate drainage and that is sufficiently smooth and low enough in gradient to be placed in class 1, but it is placed in class 2 because of the limited depth above caliche.

The more general types of land classification, as described, provide the basis for the determination of irrigable acreage and, as far as land is concerned, the basis for project planning prior to the construction stage. The more detailed type, as described for the Columbia Basin, provides information necessary for detailed project planning, for the allocation of construction assessments, and for land appraisal as required by federal laws pertaining to irrigation projects. Much use is being made of the land-classification maps on the Columbia Basin project by land purchasers who are rapidly learning that the information is available. The information provided is expected to become increasingly useful as the different blocks are placed under irrigation.

CONCLUSIONS

The system of land classification described, including, as it does, the elimination of inferior (non-arable) lands from those to be irrigated and the division of the "arable" lands into classes on the basis of physical characteristics which determine utility for farming under irrigation, is unavoidably subject to errors in judgment. Every effort is made, however, to hold such errors to a minimum by basing the standards or specifications for each class on demonstrated experience on operating irrigation projects.

Much of the strength of the method lies in its singleness of purpose but a method including a larger number of classes would provide a better basis for determining suitable crops and farm practices. The work is made more useful in the latter respects than would be the case otherwise by the inclusion of a record of soil profile examinations on each land classification sheet.

The determination of the proper point of division between "arable" and "non-arable" land is not easy and is subject to much difference of opinion. Obviously the limitation of the irrigable area of an irrigation project to "ideal" land would not be to the public interest unless the water supply were only sufficient for such an area. On the other hand, the inclusion of land in the irrigable area which will not produce sufficiently well to maintain a farm family, results only in loss to the settler and to the construction agency. It appears generally safe to include, in the irrigable area, lands of a type that have remained in continued production on older projects and to exclude lands similar to those on developed projects which have been abandoned after years of trial.

DISCUSSION

R. Earl Storie,[2] Esq.—In discussing this paper it can be stated that soil technologists are extremely pleased and happy that engineers and economists are getting down to the fundamentals of land classification—the soil. As Mr. Johnston has stated, the ability to produce depends to a large degree on the quality of the soil.

Many world travelers who have studied the historical development of irrigated agriculture have questioned its permanency. Was this decadence due to wars, the loss of soil fertility, a general lack of capacity of the land to produce, or what? An inadequate inventory of the land resources before development took place may have been responsible for much of this decadence. This should be a real challenge to those working in the land-classification field. There is more arable land in San Diego County, California, than water, and it is extremely important to select areas of land that can be benefited by, and can pay for, the water. Agriculturalists are very happy that Mr. Johnston and his associates are going into the classification of land so thoroughly, because certainly there is no question but that this work should be done in advance of any construction.

Consider the question of the so-called specialized soils—those that may produce a very few specialized crops. Often these specialized soils will not pay the carrying charges, and soil specialists certainly agree with the land classifiers of the Bureau of Reclamation that the soils which will grow many different kinds of crops are the ones that will stand the test of time. It is cause for satisfaction that more rigid standards have been set up and adhered to during the 15 years since about 1927. Had the standard of land classification been as rigid 30 years ago, the Nation certainly would have less irrigation projects that stand as tombstones to the memory of unwise irrigation planning.

To aid this work further, investigators at the University of California, in Berkeley, have been supplying the land classifiers with Natural Land Type Maps covering the various parts of the state. The natural land type is a land unit having more or less uniform, stable conditions of slope, soil profile, and soil texture, and the less stable factors of drainage, salt content, erosion, nutrient level, and micro-relief.

The soil profile is probably the one factor that is least considered by land classifiers, yet it probably is the most important over a long period of time. By all means it should be very carefully considered to insure a permanent irrigated agriculture.

There seems to be some danger in using a too generalized reconnaissance soil map for land-classification purposes. In the future there will be less danger because modern soil surveys are made on a scale sufficient to show factors of soil texture, profile, slope, erosion, alkali content, drainage, etc.

Walter W. Weir,[3] Assoc. M. Am. Soc. C. E.—It was a step in the right direction when the state and federal agencies concerned with the development of new agricultural lands learned that, when the engineering problems of supplying water had been solved, there was still the question of the suitability of the land to be taken into consideration. The sequence of these two actions is of vital importance and when properly timed may avoid many disappointments.

---

[2] In charge, Soil Survey, Univ. of California, Berkeley, Calif.

[3] Drainage Engr., Div. of Soils, Univ. of California, Berkeley, Calif.

It is common knowledge that water has been made available to some lands that could not be profitably farmed even though water were free. Although it is not a recent discovery of the Bureau of Reclamation that the inherent quality of the soil is of major importance, the Bureau is not entirely without fault even in some of its later projects. As long ago as 1925 the writer was employed to make a soil classification of a Reclamation Service project as an aid in making adjustments in water charges which had been found to be out of line with the producing power of the soil.

Considerable advancement has been made in the land-classification concept since the passage of the "Fact-Finders Act" in 1924, and of course that is as it should be. Mr. Johnston has presented the results of some 18 years of Bureau of Reclamation experience in attempting to arrive at a sound basis for land classification.

The author intimates that the purpose of land classifications is to determine what lands are arable (using his definition of the word "arable"), and that this information will be used in the design of the irrigation system. Unfortunately, the timing of these land-classification surveys is faulty, and even some of the recent surveys have not been completed until after construction is well under way or completed.

For many years the University of California, in Berkeley, has urged a detailed soil survey and land classification of the East Imperial Mesa in California, an area of some 225,000 acres of desert, for which water might be made available from the All-American Canal. The classification of the soils on this mesa is an example of poor timing, as it was not until after the completion of the All-American Canal and the Coachella Branch (from which branch much of the land is to be irrigated) that the Bureau of Reclamation undertook a land-classification survey. The writer is a member of the Advisory Committee on Land Classification for this area and assisted in setting up the standards of classification. These followed substantially the system described in Mr. Johnston's paper.

The Coachella Branch was constructed with capacity sufficient to irrigate nearly 200,000 acres on this mesa. This was based on a very rough reconnaissance soil survey made in 1920, which would not now qualify as a reconnaissance land classification as described by Mr. Johnston. The detailed classification completed in 1942 places the arable lands on the mesa at a substantially lower amount—in fact, so much lower that, had the information been available sooner, the construction of a canal of substantially different cross section might have resulted. Although the writer does not have the data at hand, it is probable that a somewhat similar situation may be found in the Columbia Basin area in the State of Washington.

With regard to the East Imperial Mesa survey, the Advisory Committee was in full agreement on the standards established, having in mind the particular use that was to be made of the survey, but the Committee strongly advised that a detailed soil survey be made either before or concurrently with the land classification. This suggestion has been followed; the University of California cooperated with the Bureau of Reclamation and the two surveys were made concurrently, to the advantage of both agencies.

One criticism that may be made of the land classifications as outlined in this paper is that the procedure is such that it can be followed by engineers whose training in soils may be limited. The Bureau of Reclamation personnel consists largely of men of engineering training and it has been exceedingly slow in going far afield for men trained in other branches of science. Land classification is not strictly an engineering job and, aside from the reconnaissance type of survey, should not be made by engineers.

The writer frequently has disagreed with the Bureau of Reclamation in its contention that detailed soil survey data are not directly applicable to its needs and that the Storie Index for soil rating cannot be applied generally to soils outside of California because the basic principles used in the index are profile development and texture of the surface soil.

Closer correlation in land classification can be maintained among different areas in the same or different states through the use of the Storie Index and R. Earl Storie's "Natural Land Types" than by any method with which the writer is familiar; but they must be applied by men familiar with soil. Land classification, made for whatever purpose, is only a special adaptation of soil survey information.

Mr. Johnston's statement that soil characteristics vary so greatly that it is difficult to make a uniform application as a guide to irrigability, and his comparison of conditions in the Sacramento Valley and eastern Montana, will hardly support a contention that detailed soil surveys are not the most logical basis for land classification. This contention may have some merit if the classifiers are not soil trained, but it certainly is not true if a little closer coordination could be secured between the engineer and the soil technician.

It has been found in the work of Mr. Storie and the writer at the University of California that, the more detailed the soil survey, the more accurately a land classification can be made. Their most severe criticism has come from attempts to make classifications in the absence of up-to-date soil data. By up-to-date soil data is meant a detailed soil survey which not only delineates and describes the soil profile in terms of its development and texture of the various horizons and strata, but also contains information on alkali, drainage, water-holding capacity, slope, and erosion. Many of the published soil survey reports are admittedly not satisfactory for the purpose, and only the most recent surveys are adequate. This condition is only to be expected, however, as soil surveying as well as land classification has developed rather rapidly, from a modest beginning, into a science.

The writer can agree with Mr. Johnston in his statement that future drainage requirements on new irrigation projects are difficult and often impossible to determine in advance. He has never fully agreed with some persons (not engineers) who have advocated the construction of drainage works at the same time as the construction of irrigation works. On the other hand, a knowledge of the soil, its age, or profile development, mode of formation, parent material, and other features that may be furnished by a soil survey are a material aid in predicting what lands may be subject to seepage, waterlogging, or salt accumulation, and their placement in the proper land-classification group.

W. L. POWERS,[4] ESQ.—The land-classification work in which Mr. Johnston and the writer were so closely associated before and after the enactment of the 1924 amendment to the Federal Reclamation Act has been developed to a high state of precision and usefulness. Members of the five-man board of review of class 3s and class 3d lands had an opportunity to test the accuracy and value of the Columbia Basin project classification in July, 1941. A similar procedure may be used in a soil survey and classification of irrigation-project lands to be undertaken for the Venezuelan Department of Public Works beginning approximately September 15, 1942.

The usable water capacity of the soil is perhaps its most important physical property in land-classification work for irrigation. The water capacity of the soil profile used by plant roots seems to be a more useful criterion than definite limitations as to soil depth. In successful projects with surface irrigation in Northwestern United States, this should be at least 4 acre-in. Some improvement in soil profile water capacity may be effected by the use of deep-rooted, humus-building legumes and farm manures from livestock enterprises.

If irrigation is to be permanent and is to repay those financially concerned, it should be preceded by a rigid land classification. This paper agrees closely with the writer's experience.

W. W. JOHNSTON,[5] ESQ.—According to Mr. Weir, a soil survey is a better basis for the purpose defined by the paper than a land classification as made by the Bureau of Reclamation. There is no rivalry between soil surveys and land classifications as defined by this paper. They are two different things. The soil survey is probably one of the most valuable pieces of work per unit of cost that is made in land studies; but, since it is made for a large variety of uses, it provides reliable data for its direct adaptation to a "land classification" only when there are occasional changes in soils and where topography and drainage conditions do not enter importantly into the problem. In lands remaining for consideration in planning an irrigation project, uniformity of this kind is rare, and in old irrigation projects the spotted occurrence of alkaline and seeped areas likewise requires that each unit of land be classified directly in the field where the importance of seepage and topography can be considered along with differences in soil.

Many attempts have been made by the writer to adapt soil surveys to land-classification uses under irrigation but these have not proved to be reliable except for the requirements of a general reconnaissance. There are several reasons—first, soil-survey maps generally are made on so small a scale that the acreage of lands in each class cannot be computed with a sufficient degree of accuracy; second, topography is considered only in a general way; third, drainage and alkali characteristics are not considered in sufficient detail;

and fourth (perhaps most important), the men who make soil surveys generally are selected because of their technical knowledge of soils and usually do not have sufficient knowledge of or interest in the problems either of the engineer or of irrigation to delineate properly between lands of varying utility for irrigation farming. In other words, to classify land properly for irrigation farming, the classifiers must be "irrigation men" as well as "soils men." As was indicated in the paper, much of the strength of the method discussed lies in its singleness of purpose. The problem is too important to be solved by a secondary manipulation of a general study.

MOMENT BALANCE: A SELF-CHECKING ANALYSIS OF RIGIDLY JOINTED FRAMES

BY R. J. CORNISH,[1] ESQ.

WITH DISCUSSION BY MESSRS. D. D. MATTHEWS, WILLIAM A. LARSEN, A. A. EREMIN, L. E. GRINTER, B. J. ALECK, FREDERICK S. MERRITT, RALPH W. STEWART, G. W. STOKES, BRUCE JAMEYSON, R. E. BOWLES, WILLIAM MORRIS, JOHN MASON, AND R. J. CORNISH.

SYNOPSIS

The paper describes a method of analysis that has two main features: (*a*) If the end moments have been estimated previously, the estimate can be adjusted rapidly (a preliminary estimate is not essential, however); and (*b*) the arithmetical work is almost entirely self-checking.

1. NOTATION

The letter symbols in this paper are defined where they first appear and are assembled for convenience of reference in the Appendix.

2. THEORY

The method depends on an easily established relationship between the end moments in the members meeting at a rigid joint. In Fig. 1, four members of uniform moment of inertia are shown meeting at point O. The stiffness K_{ON} is equal to $\frac{I_{ON}}{L_{ON}}$, etc.

The slope-deflection relationships give rise to the following expressions for such members:

$$6\,E\,K_{ON}\,\phi_O = 2\,M_{ON} - M_{NO} + X_{ON} \qquad (1a)$$

$$6\,E\,K_{OP}\,\phi_O = 2\,M_{OP} - M_{PO} + X_{OP} \qquad (1b)$$

$$6\,E\,K_{OQ}\,\phi_O = 2\,M_{OQ} - M_{QO} + X_{OQ} \qquad (1c)$$

and

$$6\,E\,K_{OR}\,\phi_O = 2\,M_{OR} - M_{RO} + X_{OR} \qquad (1d)$$

in which E = modulus of elasticity; ϕ_O = the slope of the members at point O;

NOTE.—Published in May, 1942, *Proceedings*.

[1] Dept. of Municipal Eng., College of Technology, Manchester, England.

M_{ON} = external bending moment at end O of member ON (etc.); and X = a term that usually appears in the slope-deflection equation as

$$X = \frac{6\,A}{L^2}\,(L - \bar{x})\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(2)$$

The subscript *ON* (etc.) denotes, as before, the end O of member ON. When the moment of the transverse load about the joint under consideration is clockwise, X is positive. In Eq. 2, A is the area of a "simply supported" bending moment diagram; $\bar{x}$ is the distance of its center of area from point O; and L = the effective length of the member.

FIG. 1

Addition of Eqs. 1 shows that

$$6\,E\,(\Sigma K)\,\phi_O = -\Sigma M' + \Sigma X\,.\,(3)$$

since

$$M_{ON} + M_{OP} + M_{OQ} + M_{OR} = 0\ldots\ldots(4)$$

Then, by substitution for $6\,E\,\phi_O$ from Eq. 3 in Eq. 1*a*,

$$M_{ON} = \frac{1}{2}\left[M_{NO} - X_{ON} + \frac{K_{ON}}{\Sigma K}\,(\Sigma X - \Sigma M')\right]..(5)$$

or, in general,

$$M = \tfrac{1}{2}\,(M' - X + \kappa)\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots(6)$$

FIG. 2

in which, for simplicity,

$$\kappa = \frac{K}{\Sigma K}(\Sigma X - \Sigma M') \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

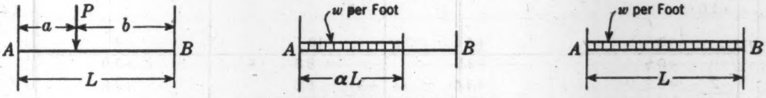
In Eq. 6, M is the external moment acting on the member at O, the joint under consideration, and M' is the moment at the outer end; all external moments are considered positive when clockwise.

The usual assumption is made that the frame can be represented by a line diagram. The prevention of linear displacements means that sidesway and longitudinal strains in the members are neglected, the problem of sidesway being discussed subsequently as a separate refinement.

3. Example

The use of Eq. 6 in frame analysis is best illustrated by an example. Fig. 2 shows a simple frame, carrying a concentrated load of 3 tons on the beam AB and a distributed load of 0.5 ton per ft on the left half of beam EF. The column ends, G, H, and K, are fixed vertically; and the stiffnesses of the various members are shown in the circles.

TABLE 1.—Values of X and the Fixed-End Moment M_F



UNIFORMLY DISTRIBUTED LOAD:
(1) Single Concentrated Load (2) On Part Span; and (3) On Entire Span

No.	A	X_{AB}	X_{BA}	$M_{F(AB)}$	$M_{F(BA)}$
1	$\frac{1}{2} P a b$	$\frac{P a b}{L^2}(L + b)$	$-\frac{P a b}{L^2}(L + a)$	$-\frac{P a b^2}{L^2}$	$\frac{P a^2 b}{L^2}$
2	$\frac{w \alpha^3 L^3}{12} \times (3 - 2\alpha)$	$\frac{w \alpha^2 L^2}{4} \times (4 - 4\alpha + \alpha^2)$	$-\frac{w \alpha^2 L^2}{4} \times (2 - \alpha^2)$	$-\frac{w \alpha^2 L^2}{12} \times (6 - 8\alpha + 3\alpha^2)$	$\frac{w \alpha^3 L^2}{12} \times (4 - 3\alpha)$
3	$\frac{1}{12} w L^3$	$\frac{1}{4} w L^2$	$-\frac{1}{4} w L^2$	$-\frac{1}{12} w L^2$	$\frac{1}{12} w L^2$

Values of X and the Fixed-End Moment M_F.—These values can be obtained at once with the aid of Table 1, and are as follows:

X_{AB} = 19.7 ft-tons; X_{BA} = − 14.1 ft-tons; X_{EF} = 28.1 ft-tons; and

X_{FE} = − 21.9 ft-tons.

$M_{F(AB)}$ = − 8.4 ft-tons; $M_{F(BA)}$ = 2.8 ft-tons; $M_{F(EF)}$ = − 11.5 ft-tons; and

$M_{F(FE)}$ = 5.2 ft-tons.

Values of X_{AB} (Table 1) are used when balancing joint A, and X_{BA} when balancing joint B. As a check on the foregoing, note that, in Table 1,

$$X_{AB} - X_{BA} = \frac{6\,A}{L} \quad \text{. . . . .} \quad (8a)$$

and

$$M_{F(BA)} - M_{F(AB)} = \frac{2\,A}{L} \quad \text{. . . . .} \quad (8b)$$

Moment Balance.—The next step is to estimate the end moments at the joints. A good designer, guided by the calculated fixed-end moments, can make a very close estimate, and in Fig. 3 the initial estimates have been underlined. The moments are balanced in Table 2, successive approximations being entered in Fig. 3 below the initial (underlined) estimates.

FIG. 3 (Initial Estimates Underlined)

In the table there is a column for each member meeting at a joint, and for each joint there is a "Σ" column also. Lines 1 to 5 show the first balance and lines 6 to 10 the second. Joint A has been considered first. In line 1, $-X_{AD}$ is zero, $-X_{AB}$ is -19.7, therefore $-\Sigma X$ is -19.7. The estimated values $(+1, +2.5)$ of M_{DA}, M_{BA} are entered in line 2, giving $\Sigma M' = +3.5$ and $\Sigma X - \Sigma M' = +19.7 - 3.5 = +16.2$. This value is distributed (line 3 and Eq. 7) between the members in proportion to their stiffnesses. (There is no object in computing distribution factors. It is only necessary to set ΣK $(= 8)$ under $\Sigma X - \Sigma M'$ $(= 16.2)$ on the top scale of the slide rule, and

the distributed moments are read over $K = 3$ and $K = 5$.) Lines 1, 2, and 3 are added to give $2M$ (line 4), and the values of M in line 5 are entered in Fig. 3. This completes the first balance of joint A.

For the first balance of joint B, the revised estimate -3.5 is used for M_{AB}; M_{EB} and M_{CB} have been estimated at $+3$ and 0, respectively; and the work proceeds as before. Joints C, D, E, and F are balanced in turn. Since DG, EH, and FK are direction-fixed at G, H, and K, the estimates of M_{GD}, M_{HE}, and M_{KF} are revised by dividing each fresh estimate of M_{DG}, M_{EH}, and M_{FK} by two.

As the original estimates were fairly close to the actual, the first balance gave results precise enough for practical purposes. However, a second balance of all the joints has been made in this example.

A few points may be noted:

(1) The accuracy of the original estimate does not affect the accuracy of the result. In the example, if the moments at all joints are initially assumed to be zero, results of the same order as those of Fig. 3 can be obtained with two balances.

(2) The fact that, to a large extent, the work is self-checking is evident. It is easy to check whether the final values of M (lines 5 and 10) at each joint add up to zero, and even if an error is made it is eliminated in subsequent balances.

(3) Although, for convenience of demonstration, the joints were balanced in the order A, B, C, D, E, F, it is probably best to start the first balance at E, and proceed in the order E, F, A, B, C, D. For the second balance some other order, which can be quickly decided by inspection, may be better.

(4) If $-\frac{1}{2}X$ and $\frac{1}{2}M'$ are used in lines 1 and 2 of Table 2 instead of $-X$ and M', line 3 will also be half as great, and the total of lines 1, 2, and 3 will be M instead of $2M$. Thus the written work for each balance can be reduced by 20% at the expense of a possible source of inaccuracy, in that one must remember each time to divide the values of M', shown in Fig. 3, by 2.

4. SUMMARY OF PROCEDURE

The basic procedure of the Method of Moment Balance may be summarized briefly as follows:

(*a*) The term X and the fixed-end moment M_F are computed for all members carrying transverse loads;

(*b*) Reasonable values are assumed for the end moments and are entered on the design sheet;

(*c*) The joints are balanced successively with the aid of Eq. 6, beginning at a member carrying a transverse load;

(*d*) When one, or more, of the members connected to a joint can be regarded as direction-fixed at the outer end, the moment must be carried over to that end. If, in Fig. 1, ON is fixed vertically at N,

$$M_{NO} = \tfrac{1}{2}(M_{ON} - X_{NO}) \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

In the case of building frames with vertical loads, X for the columns is zero, and half the moment at the top of each of the lowest columns is carried over to the base.

5. SIDESWAY

With an unsymmetrical system of vertical loads in a structure there is linear displacement of the joints as well as rotation. Except in the case of very simple frames such as the single "portal," the moments due to this displacement can be neglected, since they make very little difference to the moment at any point when all dead and live loads are taken into account.

Sidesway moments of some consequence may be caused by horizontal wind loads. The method of moment balance can be applied to such cases in a manner similar to that already described herein.

Referring to Fig. 1, if the transverse loads are omitted and the points N, P, Q, and R are given deflections Δ_N, Δ_P, Δ_Q, and Δ_R in a clockwise direction, it can be shown easily that, in general,

$$M = \frac{1}{2}\left[M' - \frac{6\,E\,K\,\Delta}{L} + \frac{K}{\Sigma K}\left(6\,E\,\Sigma\,\frac{K\,\Delta}{L} - \Sigma M'\right)\right] \;\ldots\ldots(10)$$

The analysis then follows the lines suggested by Hardy Cross and N. D. Morgan,[2] Members, Am. Soc. C. E.: "Assume as many different combinations of horizontal displacements as there are degrees of freedom of horizontal movement, and for each combination determine a set of shears corresponding to a given set of moments." This leads to the formation of as many simultaneous equations as there are floors.

The method is rather cumbersome for more than two stories, and for practical purposes another method given by Messrs. Cross and Morgan[3] provides a more rapid analysis of wind-load moments.

6. ACKNOWLEDGMENTS

The writer wishes to express his gratitude to Denis Matthews, Jun. Am. Soc. C. E., and G. W. Stokes, for their very helpful criticism and advice in the preparation of this paper.

APPENDIX

NOTATION

The following letter symbols, adopted for use in this paper, conform essentially to Standard Letter Symbols for Mechanics, Structural Engineering, and Testing Materials, prepared by a Committee of the American Standards Association with Society representation and approved by the Association in 1932:[4]

A = the area of a "simply supported" bending moment diagram due to transverse loads;

---

[2] "Continuous Frames of Re-inforced Concrete," by Hardy Cross and N. D. Morgan, John Wiley & Sons, Inc., New York, N. Y., 1932, p. 228.

[3] *Ibid.*, pp. 228–233.

[4] ASA—Z10a—1932.

a = distance of a load from the left-hand support;
b = distance of a load from the right-hand support;
E = modulus of elasticity;
I = moment of inertia; second moment of the area of a cross section;
K = stiffness ratio $\frac{I}{L}$: ΣK = sum of the stiffness ratios of members meeting at a joint;
L = effective length of a member, as designated by proper subscripts;
M = external end moment of a member, designated by the proper subscripts (considered positive when clockwise):
  M' = external moment at the outer end of a member (the terms "inner" and "outer" ends are used, respectively, for the ends of a member at, and remote from, the joint under consideration);
  M_F = fixed-end moment;
P = a concentrated load;
w = uniformly distributed load per unit length;
X = a term commonly encountered in the slope deflection analysis (see Eq. 3), a subscript—ON, for example—denoting the end O of member ON; X is positive when the moment of the transverse load about the joint under consideration is clockwise;
$\bar{x}$ = distance of the center of area of a "simply supported" bending moment diagram from the "inner" end of a member (the terms "inner" and "outer" ends are defined under M');
α = proportion of the effective span L covered by a uniformly distributed load w;
Δ = deflection of the "outer" end of a member relative to the "inner" end (the terms "inner" and "outer" ends are defined under M');
κ = an arbitrary substitution factor used to simplify Table 2 (line 3); defined by Eq. 7; and
ϕ = slope of a member at any point.

DISCUSSION

D. D. Matthews,[5] **Jun. Am. Soc. C. E.**—The "moment-balance" method of analyzing statically indeterminate frames may deservedly claim attention for two reasons: First, it involves a principle that yields an interesting picture of the structural action involved. Any set of assumed joint moments is adjusted in the analysis to satisfy statics and the geometry of continuity. "Moment balance" is essentially an automatic trial and revision process. Secondly, the practical convenience in applying the method to highly indeterminate frames with negligible sidesway is sufficient to repay the time spent in mastering the method, because of the remarkable self-checking feature of the procedure. Figs. 4, 5, 6, and 7 illustrate an example of a moment-balance analysis of a three-story frame with fifteen joints. The tables in Fig. 7 differ from those in Mr. Cornish's example only in that, for ease of comparison, the columns for the first and second balances have been placed next to each other.

For example, consider joint 3, Fig. 5, as isolated in Fig. 6. The value of X in this case is $+ 81$ (or $- X = - 81$). The balanced moment, $- 19.1$ in Fig. 7, is computed from Eqs. 5 and 6, as follows: $\kappa = \frac{10}{30.5}(81 - 26.8) = + 17.8$; and $M = \frac{1}{2}(- 81 + 25 + 17.8) = - 19.1$. This is the first balance; the result of the second balance (see Fig. 7) is 19.8. The units throughout are in ton-feet, and the analysis neglects sidesway.

For a practical analysis, blanks containing the outlines of Figs. 4, 5, and 7 could be arranged on a single sheet and a new blank filled out separately for each of the load combinations that produce maximum moments.

The writer wishes to record his thanks to Hardy Cross, M. Am. Soc. C. E., for permission to include in Fig. 7 his system for designating members by self-explanatory symbols.

OF A THREE-STORY FRAME

William A. Larsen,[6] Esq.—Much has been written the past few years on methods of obtaining moments in frames by a series of successive corrections. For any new presentation to be of value, a definitely more desirable feature than is found in the present methods should be given.

This paper presents a moment-distribution method which is a direct application of the simple slope-deflection equations. For the more or less simple frames involving no sidesway the method appears to have an advantage. It has been shown that the slope-deflection equations are convergent in character—that is, they may be solved by a series of successive corrections. The author presents the equations in such a way that the "rate of convergence" of the assumed moments to the actual moments appears to be rapid. This is the main feature of the paper. If it is shown definitely that the convergence is rapid even in case the frame has large differences in *K*-values for the different members, this method should be recommended. A quick check by the writer seemed to indicate that such is the case. This method does not, however, present tools enabling the designer to solve any new problems which are difficult now, or to solve frames more easily than by the regular moment-distribution methods. Its advantage will be in the total time required to work a frame. Where a frame will balance in 3 or 4 corrections by the regular Hardy Cross method, this method will have no apparent advantage.

That "the arithmetical work is almost self-checking," a very desirable feature, is obvious although it is not unique to this method. The other moment-distribution methods may be worked so as to be almost self-checking also. The point that any error that is introduced will be eliminated in subsequent balances is important.

It should be emphasized that this method is based on the slope-deflection equations from which the terms involving variable moments of inertia as well as the deflection of a joint (sidesway) have been omitted. This method in its present form is not applicable, therefore, to frames having haunched beams which are so common in practice today, and is, consequently, limited in application.

In the regular moment-distribution methods now used, correction for sidesway can be incorporated in the ordinary procedure. To some it will be a disadvantage to change from the author's method to some other to obtain sidesway corrections. There is extra merit to a procedure that covers both the regular moments and sidesway moments. Many designers are still looking for a method to analyze, quickly, unsymmetrical frames having members of variable moments of inertia and subjected to sidesway.

The author is to be commended on his clear and concise presentation.

A. A. Eremin,[7] Assoc. M. Am. Soc. C. E.—Distribution of moments in rigid frames or continuous beams is an interesting problem in the analysis of statically indeterminate structures. In the past few decades numerous analytical and graphical methods of distribution of moments have been developed. The methods are based on the same well-known principle of the deformation of an elastic member loaded with the moment area from the given loading. Therefore, the proximity of the methods is usually the same, and the merit of the methods varies with their simplicity and the saving of time and effort in their application to practice.

---

[6] Associate Engr., Bureau of Reclamation, U. S. Dept. of the Interior, Denver, Colo.

[7] Associate Bridge Engr., Bridge Dept., Div. of Highways, State Dept. of Public Works, Sacramento, Calif.

The slope-deflection equations for the distribution of moments converge rapidly. Therefore, various attempts have been made to develop algebraic equations that will reduce the number of steps in the computations.

To reduce the balancing operations the author, in Eq. 7, assumes the value of M'. To select a suitable approximation for M' is not always a simple matter. Often it requires preliminary analytical computations or graphical constructions. The assumed value of M' may vary from its exact value not only in magnitude but also in sign. The operations with the assumed value of M' may take more time than the additional steps required to balance the fixed-end moments in the successive approximations.

Considerable difficulty is involved in computing the moment area and its center in Eq. 2. This is especially true in relation to the haunched beams carrying irregular loading.

The graphical method of distribution of moments developed by L. H. Nishkian and D. B. Steinman,[8] Members, Am. Soc. C. E., has similar difficulty in establishing the centers in the moment areas. Complexity in finding the center of moment area in the graphical constructions was an important reason why the graphical method could not find wide application, and preference is generally given to the algebraic methods based on the fixed-end moment distribution. It is quite possible to prepare the tables and diagrams for computing the moment areas and their centers for various shapes of members and type of loading. However, these tables and diagrams will be more complicated than those prepared for computing fixed-end moments.

Distribution of moments in rigid frames or continuous beams has an important economic value in the theory of design. Therefore, the author is to be commended for his contribution toward the improvement of designing methods.

L. E. GRINTER,[9] M. AM. SOC. C. E.—This interesting and useful paper presents a method of successive approximations for analyzing rigid frames for fixed loadings. It should be noted distinctly that the procedure is one of successive approximations rather than a method of successive corrections. In this feature, it is different from the Cross method of moment distribution which has been emphasized by the writer as a convenient tool of analysis. Nevertheless, there are several points in common between these procedures.

In the author's paper the working formula (Eq. 6) is $M = \frac{M'}{2} - \frac{X}{2} + \frac{\kappa}{2}$, which is derived from the slope-deflection equations. This may lead some readers to misunderstand the background of the method, which is not the use of slopes and deflections as redundants. This will be evident if the working formula is written out without the need for mathematical derivation by a study of the physical action of the structure in Fig. 8. The moment at the end O of the member OR may be obtained as the summation of the carry-over effects

---

[8] "Moments in Restrained and Continuous Beams by the Method of Conjugate Points," by L. H. Nishkian and D. B. Steinman, *Transactions*, Am. Soc. C. E., Vol. 90 (1927), p. 1.

[9] Vice-Pres. and Dean, Graduate School, Illinois Inst. of Technology, Chicago, Ill.

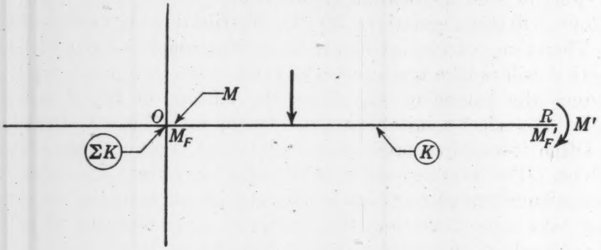

FIG. 8.—DERIVATION OF BASIC FORMULA

at that point of the moments applied at R $\left(\text{that is, } \frac{M'}{2} \text{ and } \frac{M'_F}{2}\right)$ plus the fixed-end moment at the end O plus the balancing moment at O for the member OR when the joint is allowed to rotate. Thus, without reference to sign, one may write

$$M = \left[\frac{M'}{2}\right] + \left[M_F + \frac{M'_F}{2}\right] + \left[\frac{K}{\Sigma K}\left(\frac{\Sigma M'}{2} + \Sigma M_F + \frac{\Sigma M'_F}{2}\right)\right] \quad (11)$$

In Eq. 11, the three terms enclosed in brackets will be found to correspond exactly to the author's definitions of the three terms of his Eq. 1. Signs, of course, follow automatically if some such rule is adopted as "a positive moment tends to rotate the adjacent joint clockwise."

After Eq. 6, or Eq. 11, is established, the author's procedure is simple and convenient since it permits the operator to shorten the convergence by exercising his judgment. In many problems, it is true that the final moments can be "guessed" with reasonable accuracy, and these become the first M'-values in Eq. 11. The values of M_F and M'_F, being fixed-end moments, are known exactly. Evidently, all values of M can then be computed by repeated use of Eq. 11. It must be realized, of course, that a given moment is an M-value for that point but an M'-value when the moment at the far end of the member is being computed.

This method of analysis has many points in its favor, particularly if the procedure is brought clearly into view by eliminating the unnecessary terms X and κ. On the other hand, it lacks the close association with the deformations of the structure that is so evident in the Cross procedure. For example, it is convenient and almost necessary to follow the author's procedure of placing the calculations in tabular form, rather than upon the diagram of the structure, since a term such as the author's X or κ is not an individual moment but a combination of a number of moments that are best selected from a well-organized table. The writer tried the other procedure of writing all moment terms upon an outline of the structure but found it not entirely practicable. Also, there were a great many more terms and many more calculations than are involved in an analysis by the usual method of balancing moments.

To be more useful than the regular procedures of balancing moments, this method should be preceded by a careful estimate of the moments. If the moments can be estimated so accurately that only one revision becomes necessary, the method might be faster than any other in common use; but, if the method is for use by inexperienced designers, several revisions of moments will be necessary and the procedure will be rather lengthy.

The self-correcting feature of the method deserves comment. Since this is a method of successive approximations, an error in recording a moment will be corrected in the succeeding revision. In this direction the method has merit. The check of $\Sigma M = 0$ at each joint, of course, is not an independent check because this tool is used as one part of the procedure of analysis. An error in computing a fixed-end moment, in computing K or ΣK, or in sign may not be discovered. In these computations, care must be exercised, as always.

The writer suggests that this method should be given the author's name because the title "Moment Balance" or "Balancing Moments" has been used for years as an alternate to "Moment Distribution" to designate the Cross method, or its variations, based upon successive corrections.

B. J. ALECK,[10] JUN. AM. SOC. C. E.—"Moment balance" may be extended to apply to members of variable moment of inertia and to some other special cases. Let all moments and joint rotations be considered positive when they are counterclockwise at the ends of the member. Let: $(K_f)_{AB}$ = stiffness at A when B is free to rotate; $(M_f)_{AB}$ = fixed-end moment at A when B is free to rotate; and C_{AB} = carry-over factor from A to B. Then

$$M_{AB} = (M_f)_{AB} + C_{BA}\, M_{BA} + (K_f)_{AB}\, \phi_A \ldots\ldots\ldots\ldots (12a)$$

and

$$\Sigma M_{AX} = \Sigma[(M_f)_{AX} + C_{XA} M_{XA}] + \Sigma(K_f)_{AX}\, \phi_A = 0 \ldots\ldots (12b)$$

at joint A; and

$$\phi_A = -\frac{\Sigma[(M_f)_{AX} + C_{XA} M_{XA}]}{\Sigma(K_f)_{AX}} \ldots\ldots\ldots\ldots (12c)$$

The procedure from this stage follows the outline set up by Mr. Cornish: $(M_f)_{AX}$ is computed; $C_{XA}\, M_{XA}$ is approximated and used in Eq. 12c to find ϕ_A; and ϕ_A is then used in Eq. 12a to find the moments at joint A.

It should be emphasized that members with known conditions at the far end can be represented with "modified" stiffness and fixed-end moment, in a manner identical with that used in "moment distribution." For such members,

$$M_{AB} = (M_{MF})_{AB} + (K_M)_{AB}\, \phi_A \ldots\ldots\ldots\ldots\ldots (13)$$

when $(M_{MF})_{AB}$ = modified fixed-end moment and $(K_M)_{AB}$ = modified stiffness.

Since Eq. 13 is of the same form as Eq. 12a, it may be used whenever convenient as a substitute, and relieves one of estimating M_{BA} before M_{AB}

---

[10] Research Engr. (Materials and Structures), Curtis Wright, Plant 5, Buffalo, N. Y.

is known. The moments at the far end of such members are found, using the modified carry-over factors.

For common members, data compiled for use with the moment-distribution method can be modified to evaluate all the terms used in Eqs. 12 and 13. For uncommon members, they can be evaluated from the properties of the proper $\frac{M}{E\,I}$-diagram.

Mr. Cornish's method provides a check in one cycle on answers obtained by any method. To the writer, this feature alone seems sufficient reason for engineers to learn the principles of "moment balance."

FREDERICK S. MERRITT,[11] JUN. AM. SOC. C. E.—The method of analyzing continuous structures by moment balance has two main features to recommend it. First, by enabling designers to estimate final moments, considerable work may be saved. Second, its self-checking character may also save time, in that errors may be either immediately located or neutralized by further balancing. Accounting for sidesway moments is as much of a handicap in other methods as it is in this.

The method of moment balance may be applied in a somewhat different form with the advantage of ease of generalization and saving in computation. Let: α = six times the rotation at one end of a simply supported beam of unit length and least $K = \frac{I}{L} = 1$ due to a unit moment applied at that end; β = six times the rotation at one end of this beam due to a unit moment applied at the other end; K = the ratio of least moment of inertia to span length; M = actual end moment minus fixed-end moment; and ϕ = the rotation at the end of any beam. Clockwise moments will be considered positive and counterclockwise moments negative. Then, referring to Fig. 1, in general, neglecting deflection at beam ends:

$$6\,E\,K_{ON}\,\phi_O = \alpha_{ON}\,M_{ON} - \beta_{ON}\,M_{NO} \qquad (14a)$$

$$6\,E\,K_{OP}\,\phi_O = \alpha_{OP}\,M_{OP} - \beta_{OP}\,M_{PO} \qquad (14b)$$

$$6\,E\,K_{OQ}\,\phi_O = \alpha_{OQ}\,M_{OQ} - \beta_{OQ}\,M_{QO} \qquad (14c)$$

and

$$6\,E\,K_{OR}\,\phi_O = \alpha_{OR}\,M_{OR} - \beta_{OR}\,M_{RO} \qquad (14d)$$

Divide each equation by its value of α_O and let $S = \frac{K}{\alpha}$ and $C = \frac{\beta}{\alpha}$. Note that C is the carry-over factor toward O for the beam, considering it as fixed-ended. Summing Eqs. 14 yields:

$$6\,E\,\phi_O\,\Sigma S_O = \Sigma M_O - \Sigma(C\,M') \qquad (15)$$

in which M' is the change in the fixed-end moments at the far ends. Since $-\Sigma M_O = \Sigma M^F{}_O$ (the sum of the fixed-end moments at O due to loads)—

$$6\,E\,\phi_O\,\Sigma S_O = -\left[\Sigma M^F{}_O + \Sigma(C\,M')\right] \qquad (16)$$

---

Final moment		+1.0	−1.5	+0.5	....	+3.5	+1.9	+3.5	−8.9	....	+3.8	−1.5	−2.3	....

Substituting Eq. 16 in Eq. 14*a*:

$$M_{ON} = C\, M_{NO} - \frac{S_{ON}}{\Sigma S_O} \left[\Sigma M^F{}_O + \Sigma (C\, M') \right] \ldots\ldots\ldots\ldots (17)$$

Using Eq. 17, the method of moment balance may be applied to continuous frames containing beams of variable moment of inertia. The final moments are obtained by adding the results of the last balance to the fixed-end moments. For beams of constant moment of inertia, Eq. 17 becomes:

$$M_{ON} = \tfrac{1}{2}\, M_{NO} - \frac{K_{ON}}{\Sigma K_O} \left(\Sigma M^F{}_O + \tfrac{1}{2}\, \Sigma M' \right) = \tfrac{1}{2}\, M_{NO} - m \ldots\ldots (18)$$

in which

$$m = \frac{K_{ON}}{\Sigma K_O} \left(\Sigma M^F{}_O + \tfrac{1}{2}\, \Sigma M' \right) \ldots\ldots\ldots\ldots\ldots\ldots (19)$$

Using Eq. 18, the frame in Fig. 2 was analyzed for a comparison of results (see Table 3). The same changes in fixed-end moments as assumed by the author were also taken as a preliminary estimate. Joint A was balanced first. One half the change at the far ends was recorded for AD and AB and the sum placed under the sigma. This sum was then added to the fixed-end moment (in this case zero), and the result, entered in Table 3, was distributed, with sign changed, to AD and AB in proportion to their *K*-values. The change in the fixed-end moment was obtained by adding the two values entered for each member. If the final moment were desired at this stage, the addition would include the fixed-end moment, and the change in moment would not be entered. It will be noticed that at the end of the first balance results agreeing with those of the author were obtained.

The method of moment balance has the same disadvantage in practical application as other methods of analysis by converging increments—that is, in locating loads for maximum moment. Because of the unknown end conditions in interior spans, it is difficult to apply these methods to problems of moving loads.

Ralph W. Stewart,[12] M. Am. Soc. C. E.—The "Synopsis" of this paper states that the trial and revision procedure which it describes is rapid and that the arithmetical work is almost entirely self-checking. These claims are attractive and led the writer to experiment some with the author's demonstration problem shown in Fig. 2.

Table 4 shows the results of three independent solutions of this problem, as well as the final moments computed by the author. For the practical design of a building frame of this type it is necessary to consider various combinations of loading, including wind or earthquake loads. This requires that the frame be solved for the effect of a fixed-end moment at each of its joints. The first solution in Table 4 gives the effect of each individual fixed-end moment and is carried to an accuracy of 0.01 ft-ton. This first solution was performed without the use of simultaneous equations and without the use of any kind of successive approximations.

FIG. 9.—FIFTY-MINUTE SOLUTION BY H. O. SPRINGER

The solution by H. O. Springer (see Fig. 9) was performed by conventional end-moment distribution in 50 min, including the time required to make the sketch and write on it the stiffness factors and fixed-end moments. The solution by L. Blume (see Fig. 10), which is of the same order of accuracy as the author's two-place solution, required only 15 min after the sketch showing stiffnesses and fixed-end moments was prepared.

The author deserves credit for having made a scholarly investigation of the analysis of rigidly jointed frames. However, between the superior speed of the conventional end-moment distribution solution and the superior quality of the first solution in Table 4, it appears to the writer that the author's method is encircled so that it has no useful field.

FIG. 10.—FIFTEEN-MINUTE SOLUTION BY L. BLUME

It also may be mentioned that for one-story structures the "quality" type of solution will be considerably faster than either end-moment distribution or the author's method.

G. W. STOKES,[13] ESQ.—One of the most useful applications of Mr. Cornish's original adaptation of the slope-deflection formulas occurs in connection with moment calculations for "ordinary building" frames.[14] No definition of such frames appears to be available but, no doubt, essential features are that the beams shall be prismatic (or that the inertia moment of any haunch, considered as a rectangular section, shall not be greater than the assumed inertia moment of the midspan tee section) and that sidesway due to vertical loading is negligible.

The number of moment calculations for a complete multi-story building frame is usually large and is magnified by the alternative arrangements of superload which give maximum moments. Since the relative K-values are in the first place unknown, it is common practice to proceed by means of intelligent approximation of these values, based in the first place on consideration of fixed-

κ = a substitution factor
M = final moment

end beam moments and statical reactions, afterward adjusted by the simplest possible calculations of end moments for limited sections of the frame. For these preliminary estimates of moments it is doubtful whether any simpler method has been found, or is likely to be found, than single-cycle distribution and carry-over of individual fixed-end moments for dead load, summation of such moments and further summation by the addition of moments for alternative superload arrangements, obtained by proportion from the relation of superload to dead load.

It is in the final stage of calculation, which follows the preliminary estimates, that the characteristics of the "moment-balance" method appear to be most valuable—namely, rapid convergence, simple tabulation and ease in checking. The method is somewhat lengthy if several balances are required. It is important, therefore, that the estimates of the M'-values should be reasonably close.

By the insertion, in their appropriate columns, of the M'-values and K-values already obtained, one "balancing" operation is usually sufficient to give results accurate enough to form the basis for design.

A point in favor of Mr. Cornish's method, for many designers, will be its clear derivation from the well-known slope-deflection formulas. The substitution of values in formulas is a practice well established among structural engineers, a fact which no doubt explains the many efforts to express the processes of moment distribution in terms of symbols.[15]

An example of a section of a simple building frame is shown in Table 5. The M'-values and K-values are those obtained by previous approximation. Check calculations made by the usual slope-deflection and full moment-distribution methods give results practically identical with the M'-values shown in Table 5. The necessary summations are common to any method and are not given.

Bruce Jameyson,[16] **Assoc. M. Am. Soc. C. E.**—To evaluate properly the relative merits of the new Cornish Method of Moment Balance the fact should not be overlooked that the Cross Method of Moment Distribution will accomplish nearly the same results and, in addition, as stated by the author, will include the sidesway feature more readily for complicated frames. When starting with the correct answers, moment distribution will balance most types of problems in one cycle, thereby partly checking these answers. If the answers are incorrect, one cycle will so indicate and usually will show the approximate location of the error or errors. Errors will be corrected in one or more cycles. If fair starting values are assumed, convergence is rapid. The accuracy (decimal places) of the trial answers may be increased. The foregoing statements apply equally well when sidesway is considered. To illustrate, the author's example is worked by moment distribution, using his starting trial answers.

Example.—Consider the example and frame shown in Fig. 2. The computations in Table 6 are almost self-explanatory. Joint rotation moments

---

[15] For example, see "Recommended Practice and Standard Specifications for Concrete and Reinforced Concrete," Rept. of the Joint Committee on Standard Specifications for Concrete and Reinforced Concrete, *Proceedings*, Am. Soc. C. E., June, 1940, Pt. 2, Appendix 2, p. 110.

[16] Associate Prof., Civ. Eng., Univ. of California, Berkeley, Calif.

(M_R-values) were computed for the six upper joints, using the author's assumed starting answers in the girders and fixed-end moments (F-values). For example, for joints A and B:

$$M_{AB} + \tfrac{1}{2} M_{BA} = \text{answer} - F = 3.0 - 8.44$$

and

$$\tfrac{1}{2} M_{AB} + M_{BA} = \text{answer} - F = 2.5 - (-2.81)$$

Solving, joint rotation moments (M_R-values) are:

$$M_{AB} = -7.46$$

and

$$M_{BA} = 4.04$$

These two moments are the controlling moments for rotation of joints A and B, respectively. Then

$$M_{AD} = \frac{3}{5} \times (-7.46) = -4.48$$

$$M_{BE} = \frac{4}{5} \times 4.04 = 3.23$$

and

$$M_{BC} = \frac{5}{5} \times 4.04 = 4.04$$

In actual practice (except when checking answers, say, from another method) these joint rotations would not be computed, as in Table 6, but would be guessed directly instead of guessing the trial answers. Some work thus would be saved. Also, little would be gained by attempting to guess joint rotations at joints C and D, which are far away from any load. This, then, becomes simply the general application of the arbitrary joint-rotation, short-cut method treated by Professor Cross and applied by him to a very special case.[17] The rotation moments may be applied to any or all joints, but, when the control rotation moment for one end of one member has been computed or assumed, the M_R-values for all other members framing into the joint must be in accordance with relative stiffnesses (K-values). This follows from the fundamental definition of stiffness—that is: "The moment at one end of a member necessary to produce unit rotation of the same end, opposite end fixed (or free) and with no relative end deflection." Carry-over factors from these rotation moments (C_R) must be applied to opposite ends of members thus rotated. Note that, for member BA, $F + M_R + C_R$ = assumed estimated starting answer. Table 6 shows "Close answers at end of four cycles" (work of third and fourth cycles not shown). These answers are correct to a maximum possible error of 0.02.

The following facts may be noted:

(*a*) At the end of the first cycle results by moment balance are more accurate than by moment distribution.

Author's answers at end of two cycles	....	−3.5	+3.5	−3.0	+0.8	....	+2.2	−0.1	+0.1	....

(*b*) At the end of the second cycle both methods yield results of about the same accuracy (nine differences of 0.1 in each case).

(*c*) Original starting answers (moments) have been roughly checked, and errors and mistakes in these starting answers have been corrected.

(*d*) The computations (except the original answers) were carried by slide rule to two decimal places, thereby increasing the accuracy of the four-cycle answers. Some of the computations by moment balance could not have been obtained to this accuracy by slide rule.

(*e*) One cycle of moment distribution, other than the first, involves smaller numerals and less work than for moment balance. The first cycle of both methods involves roughly the same amount of work when M_R-values are guessed, in moment distribution, instead of the answers.

(*f*) In this problem, sidesway corrections (fixed-end moments *f*), if desired, would be added directly after the carry-over values and would be based upon the subtotals at this stage.[18] In either case, if the starting answers were correct, all balancing moments would be zero, and the first and only cycle would partly check the assumed answers. The *f*-values, for this problem,

[a] Controlling moment for joint.

are so easily computed that there usually would be little excuse for neglecting sidesway.

Conclusion.—It is the writer's opinion that the advantage is with moment distribution, at least in so far as the solution of the author's particular example is concerned. The writer believes, however, that the author has made a valuable contribution and that his method will find a permanent place in the field of structural analysis.

R. E. Bowles,[19] **Esq.**—The theory upon which this paper is based is a simple one and one that has now probably become familiar to those interested. It does not involve any intermediate assumptions that are not in accordance with the actual structure. Thus it avoids the complication of locking and releasing the joints. The paper is a valuable contribution to the subject for the following reasons:

1. The process solves, directly, for the quantity required—that is, the moments, and not the slopes.

---

[19] Dept. of Building, College of Technology, Manchester, England.

2. It is simple in operation, largely self-checking, and error-eliminating.

3. It is considered to be an advantage that the resulting calculations are not written on the frame diagram, but are written in a table considerably easier to arrange than that of moment distribution for a complicated structure. It avoids the addition of the results of successive stages, which in moment distribution involves the summation of numerous quantities of opposite sign.

4. As the order of the "balances" is unimportant it is possible to concentrate on those parts of the structure where given loading produces maximum effect.

5. It permits the experienced designer to minimize work by inserting intelligent forecasts of the desired results, whereas less experienced designers may obtain equally accurate results with slightly more labor.

6. A few simple examples that have been solved by this method suggest that even without experience the designer finds it less laborious and quicker than other methods.

7. The practical user will probably appreciate that at each successive stage the required moment is seen clearly without resort to summation.

8. Although the method, as published, does not directly accommodate varying moments of inertia or sidesway, it may still be applied to many practical problems where the effects of these factors are frequently neglected.

The foregoing conclusions have been confirmed mostly by actual computations for a simple frame, which the writer had previously solved, for comparison, by other methods.

William Morris,[20] Esq.—Mr. Cornish appears to be justified in his claim to have established a method which is self-checking, and which gives quite a rapid solution of rigid frames. The writer tested the method on several frames, using assumed end moments which were obviously a bad guess, and even used moments of the wrong sign. It was found that three balances gave results which were sufficiently accurate in the worst case of assumption.

It does not seem necessary, however, to calculate the values of X by use of the formulas given in Table 1, as the fixing moments can be used directly for this purpose. To avoid the excessive amount of arithmetic which appears to be involved, the writer suggests the following form of solution which will, no doubt, commend "moment balance" to those engineers who are familiar with the moment distribution form of solution. For example, Eq. 5 may be written in the form

$$M_{ON} = \frac{1}{2} M_{NO} - \frac{K_{ON}}{\Sigma K}\left[\sum\left(-\frac{X}{2}\right) + \sum \frac{M'}{2}\right] + \frac{1}{2}\left(-X_{ON}\right) \ldots (20)$$

This indicates a process similar to moment distribution as follows:

(*a*) Assume moments at the ends of the members remote from the joint under consideration;

(*b*) Carry half these moments over to the joint;

(*c*) Sum the latter together with $\sum\left(-\frac{X}{2}\right)$ and distribute to each member in proportion to their K-values; and

---

With Matthews and Mumby, Manchester, England.

(*d*) Add the results obtained (not forgetting to include $-\frac{X}{2}$ for those members which are loaded) to give the final moments. The process is continued around the frame as shown in the paper. It is to be noted that the values of $-\frac{X}{2}$ for each end of a loaded member can be obtained from the fixing moments by carrying over to the far end half the moment of the near end and changing sign. Sum the results to give $-\frac{X}{2}$ for each end.

It seems preferable to determine the values of $-\frac{X}{2}$ for all loaded spans first, although, for a building frame designed by loading only one span at a time to give maximum moments, two values only are required. This means that the values of $-\frac{X}{2}$ are only included in the balancing twice, as Eq. 20 reduces to the form

$$M_{ON} = \frac{1}{2} M_{NO} - \sum \frac{M'}{2} \quad \text{.................... (21)}$$

for the remaining joints.

The process is illustrated in Fig. 11 on which values of $-\frac{X}{2}$ have been kept clear of the calculations and the assumed moments have been written at

the side of the table. The example chosen is that used by Mr. Cornish and the results at each joint are naturally identical with those of the author, who shows that they "self-check." The method is easily adaptable to portal frames without sidesway and continuous beams and, of course, can be used for haunched beams when the fixed-end moments and stiffness values have been ascertained.

The practical usefulness of the method for problems involving sidesway is not apparent.

JOHN MASON,[21] ESQ.—There are two points suggested by this most interesting paper, upon which the writer would like to comment:

(1) Why introduce a new concept "*X*" in addition to the fixed-end moment M_F? The fixed-end moment must be found as a guide to the estimate of the end moment, and it will be shown that it can be re-used just as easily in the moment balance as the new expression.

(2) Any saving in labor by this method depends on a reasonable initial estimate of the end moments which, it is submitted, is more than offset by the certainty of working methodically to the result by methods that do not depend on any such estimate.

[21] Cons. Engr., London, England.

Using the method of "allocated moments" presented by the writer[22] in 1940, an alternate solution of the example given in Table 2 (using the same sign convention and notation) is given in Table 7.

The essential feature of the method of allocated moments consists in finding the angular rotation of the joint or, for convenience, a value called the "joint moment," which is a measure of the angular rotation of the joints, being related to it by the equation:

$$\text{Joint rotation} = \frac{\text{Joint moment}}{4 \times \text{joint stiffness} \times \text{E}} = \frac{\text{Joint moment}}{4\,E\,\Sigma K} \quad \ldots\ldots (22)$$

in which the "stiffness of the joint" equals the sum of the stiffness of all members radiating from that joint.

The joint moment is found by taking the sum of the fixing moments and adding algebraically to this value a series of allocated moments, each allocated moment being equal to $-\frac{1}{2}$ the adjacent joint moment distributed in proportion to the stiffness of the members at that joint. The allocated moments are the same as the "carry-over" moments in "moment-distribution" methods. In the concise method on which Table 7 is built, however, the moments totaling +3.7 (allocated to joint B in the first allocation) are first added to the fixed-end moment, +2.8, and the sum, +6.5, is allocated in bulk to the adjacent joints.

Once the rotation of the joint has been established, the end moments follow from the slope-deflection relationships:

$$\begin{aligned} M_{ON} &= M_{F(ON)} + 4\,E\,K_{ON}\,\phi_O + 2\,E\,K_{NO}\,\phi_N \\ &= M_{F(ON)} + K_{ON} \times \frac{\text{Joint moment}_O}{\Sigma K_{ON}} + \frac{K_{NO}}{2} \times \frac{\text{Joint moment}_N}{\Sigma K_{NO}} \quad \ldots (23a) \end{aligned}$$

$$\begin{aligned} M_{NO} &= M_{F(NO)} + 4\,E\,K_{NO}\,\phi_N + 2\,E\,K_{ON}\,\phi_O \\ &= M_{F(NO)} + K_{NO} \times \frac{\text{Joint moment}_N}{\Sigma K_{NO}} + \frac{K_{ON}}{2} \times \frac{\text{Joint moment}_O}{\Sigma K_{ON}} \quad \ldots (23b) \end{aligned}$$

or, in general,

$$M = M_F - \mu - \frac{\mu'}{2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Now the sum of the allocated moments is equal to

$$\frac{\mu'}{2} = \frac{K_{NO}}{2} \times \frac{\text{Joint moment}_N}{\Sigma K_{NO}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (25)$$

The method is therefore self-checking by comparison of

$$\frac{\mu'}{2} = \frac{K_{NO}}{2} \times \frac{\text{Joint moment}_N}{\Sigma K_{NO}}$$

from Eq. 23*a* with half the complimentary term $\mu = K_{NO} \times \frac{\text{Joint moment}_N}{\Sigma K_{NO}}$ from Eq. 23*b*.

---

[22] *Journal*, The Inst. of Structural Engrs., April, 1940, p. 577; for discussion, *ibid.*, March, 1941, p. 43.

It should be noted that, since the rotation at a fixed end is zero, there is no allocated moment from a fixed end; hence, the entries in Cols. DG, EH, and FK are all zero.

Applying Eq. 24 to the moment balance system, the allocated moments $\left(\frac{\mu'}{2} = 2\,E\,K_{NO}\,\phi_N\right)$ are first estimated and added algebraically to the fixing moments to find the joint moment, which is then balanced. If, on comparison of $\mu = 4\,E\,K_{NO}\,\phi_N$ with $\frac{\mu'}{2} = 2\,E\,K_{NO}\,\phi_N$, the solution is not sufficiently accurate, the process is repeated, using one half of the last-found value of μ instead of $\frac{\mu'}{2}$ as the allocated moment in the next balance.

The computation is now as shown in Table 8, the order of balancing being joints B, D, F, A, C, and E and the initial estimates for $\frac{\mu'}{2}$ being obtained by balancing the fixed moment directly. Thus, +8.4 from joint A balances into AD = + 3.2 and AD = + 5.2. The initial estimates are underlined in Table 8. Values from the revised estimates have been used as soon as found.

It will be seen that, although the second balance is quite close enough for practical purposes, the calculation has been taken to the third balance as a check. It also will be noted that the values in the moment balance (Table 8) for $\frac{\mu'}{2}$ and Σ are in all cases the same as the sum of the figures at the corresponding stages in the method of allocated moments (Table 7).

It should be pointed out that the example taken is a very simple one, the incidence of the loading being such that the allocated moments in any one column are always of the same sign and that the joint moment, therefore, is always increasing in absolute value. This would not necessarily be the case if all the bays were loaded.

The outstanding merit of the method suggested by Mr. Cornish is that it enables a very rapid first approximation to be made of the moments at a joint in terms of the members immediately adjacent to that joint. It is of great value in the initial stages of a design, and perhaps at a time when the other members have yet to be designed, to be able to arrive at this first approximation. Any such approximation can also be checked and corrected, as the design of the members proceeds, by taking out subsequent balances.

It is submitted, however, that the introduction of the concept "X" is unnecessary.

Although it is admitted that members remote from the joint under consideration only affect the moments at that joint in a secondary degree, clearly any method which achieves quickness by discarding certain factors must be limited in that respect.

R. J. CORNISH,[23] ESQ.—The paper originated in an attempt to adapt, to structural frameworks, methods of successive approximation which had proved successful in the study of flow in networks of pipes.[24] In the latter case, there are two basic facts: At a given junction the head is the same in all pipes; and the total quantity entering equals the total quantity leaving. In a rigid frame, at any joint the angle of slope is the same for all members, and the sum of the positive moments equals the sum of the negative moments. Here the analogy appears to end. There seems to be nothing in a structural member which corresponds to the flow of water through a pipe, and it is difficult to visualize a moment "entering" a frame as water enters a pipe network. The quantity X was an attempt to represent the application of moments to the frame. This approach probably explains why the writer failed to notice that X can be simply expressed in terms of the fixed-end moments $X = -2\,M_F + M'_F$, and he is indebted to Professor Grinter and Mr. Morris for making this clear. Table 3, by Mr. Merritt, in which the term X does not appear, might well supersede Table 2. It is preferable to that suggested by Mr. Mason, although it is useful to have his variation on record.

Messrs. Aleck and Merritt have adapted the method to members of varying section, thus answering an objection raised by Messrs. Larsen and Eremin. Messrs. Matthews and Morris have shown that the calculations can be tabulated "on the frame." The writer considers a separate tabulation to be clearer, an opinion with which Mr. Bowles expresses agreement. The time factor, mentioned by Messrs. Larsen and Stewart, is admittedly an important one, but the time occupied in checking work, and in locating suspected mistakes, should be taken into account, although it is hardly possible to estimate it. Any one who has had the task of checking a frame computation knows the labor involved and the difficulty of deciding whether discrepancies are serious. Messrs. Aleck and Stokes both refer to the value of moment balance in this connection. It has the merit of indicating the magnitude of errors in addition to locating them.

The self-checking feature of moment balance is an advantage to those engineers whose arithmetical accuracy is not above reproach, and for any one there is less mental strain when this feature is present. For the same reason the additional written work on which Professor Grinter comments may not be entirely a disadvantage. As he remarks, it is partly because this is a method of successive approximation rather than of successive correction, and partly because operations which would be performed mentally in other methods are included in the table.

---

[23] Dept. of Municipal Eng., College of Technology, Manchester, England.

[24] "Analysis of Flow in Networks of Conduits or Conductors," by Hardy Cross, Univ. of Illinois Eng. Experiment Station, *Bulletin No. 286*, 1936; and "Analysis of Flow in Networks of Pipes," by R. J. Cornish, *Journal*, Institution of Civ. Engrs., December, 1939, p. 147.

The writer cannot agree with Mr. Stewart that the first method of Table 4 gives results of superior "quality." Any method of successive approximations or successive corrections can give results to any number of decimal places provided that enough balances are made; but few designers think it worth while to get meticulously "accurate" answers, considering that the appropriate values of E, I, and L can be known only approximately. The important thing is to find a method that will quickly give an answer that is accurate enough for practical purposes.

Mr. Jameyson's adaptation of the Cross method of analysis to the correction of initial estimates is interesting and valuable; it may be that the most useful service the paper has rendered was to provoke this contribution.

A defect of moment balance, as presented in the paper, was that correction for sidesway was awkward; this difficulty has now been overcome.

Section 5 of the paper outlines a method of computing sidesway moments, involving the solution of as many simultaneous equations as there are floors. This makes the method unsuitable for general use. This limitation was suggested by Messrs. Larsen and Bowles. In the following procedure, this disadvantage is eliminated. Each story is given an arbitrary initial deflection and the resulting moments are balanced with the help of Eq. 10; the deflections then are adjusted to make the sums of the column-end moments equal to the sidesway moments. One repetition of this process usually gives sufficient accuracy for practical purposes.

As a simple example, the frame of Fig. 2 will be analyzed for the horizontal forces shown in Fig. 12. With 1.5 tons at A and 2.0 tons at D, the shears in the upper and lower stories are 1.5 tons and 3.5 tons, respectively. If AD is 15 ft and DG is 20 ft, the corresponding sidesway moments are 22.5 ft-tons and 70.0 ft-tons.

It can be assumed as a first approximation that, in its deflected form, Col. ADG remains a straight line. (This is close to the truth for tall, regular frames,[25] although in this example it is far from true; however, the error is eliminated rapidly.) Then, if Δ is the relative displacement of the top and bottom of a column of length, L, $\frac{\Delta}{L}$ has the same value for each story, and the initial values of $\frac{6\,E\,K\,\Delta}{L}$ must be proportional to K, the stiffness ratio. Since at first one is concerned only with relative deflections, it is convenient to begin by making $\frac{6\,E\,K\,\Delta}{L}$ equal to K. The slope deflection equations show that, when the ends of a member are deflected without rotation, the moment induced at each end is $\frac{-\,6\,E\,K\,\Delta}{L}$; the initial column moments are therefore simply the stiffness ratios K. These are entered in Fig. 12 beside each column, and are thus the moments resulting from deflection of the frame without rotation of the joints. Since the frame is symmetrical, only one half of it need be considered, and moments needed in the right-hand half can be inserted by symmetry.

---

[25] "Theory of Modern Steel Structures," by L. E. Grinter, Macmillan, New York, N. Y., 1937, Vol. 2, p. 168.

In the next step the moments are balanced; that is, rotation without deflection takes place. The balance could be started from the K-values already entered, but time is saved by a rough preliminary adjustment, reducing the moments of the outer columns by rather more than those of the inner columns. Very little care is needed except where a member is direction-fixed at one end, in which case the moment at that end must be altered by half as much as the moment at the other end. For instance, when M_{DG} is reduced from -4.0 to -3.0, M_{GD} must be reduced to -3.5.

FIG. 12

After the preliminary column moments have been selected, the corresponding beam moments are entered in Fig. 12. These rough estimates have been underlined to show that they form the start of the balance.

The balance closely resembles that given in the paper, except that Eq. 10 is used instead of Eq. 6, and, thus, in Table 9, $\frac{-6EK\Delta}{L}$ takes the place of $-X$ in Table 2.

Fig. 13

Joint D was first balanced. As in the paper, M' refers to moments at ends of members remote from D—that is, M_{AD}, M_{ED}, and M_{GD}. The items in lines 1 and 2 of the Σ-column are added with the sign changed, and the result (+8.5) is distributed to the members in proportion to their stiffnesses. The values in lines 1, 2, and 3 are added to give line 4, which is divided by 2 to give M_{DA}, M_{DE}, and M_{DG} (line 5). The values are entered in Fig. 12 at D, and M_{GD} is altered by half as much as M_{DG}. The remainder of the first balance, in the order, *E*, *A*, *B*, is done in the same way.

The sidesway moment which is actually being taken by each story is now found by adding the column-end moments. Since those in CF and AD are the same, the sum for the upper story is equal to $2(-1.6 - 1.3) - 2.8 - 2.6$, which equals -11.2 (an abbreviated form of this computation is shown at the bottom of Fig. 12). All the upper-story column moments therefore must be increased in the ratio $\frac{22.5}{11.2}$. Similarly, the column moments in the lower story must be increased in the ratio $\frac{70.0}{19.1}$, and corresponding alterations must be made in the beam moments. The new values are entered in italics in Fig. 12. The values of $\frac{6\,E\,K\,\Delta}{L}$ are increased in the same ratios and are entered in Fig. 12 on the left of each column.

One more balance and adjustment of sidesway moments has been shown. The process may be repeated to give any order of accuracy desired, but wind loading is so indefinite that great precision is not necessary. For most design purposes a single balance gives enough information provided that the preliminary estimates were reasonably close; the second balance provides a general check.

The method is especially useful with regular frames of several stories. If the balance is started at the bottom, at first only rough estimates for the two lowest floors need be inserted. The results of the first balance of the bottom floor moments guide one in the next estimates, and so on. The moments at the higher floors can be written down almost before the balance is made. The adjustment of beam moments after allowing sidesway is not so obvious in a frame of several bays as in the simple example of Fig. 12, but any common sense basis is satisfactory.

Fig. 13 and Table 10 show the calculations for the lower floors of the Wilson-Maney truss.[26] These are given here because this truss has been used as a typical example for other methods,[27] with which moment balance can be compared.

In an actual computation it is better to arrange the table with the stories beneath one another, instead of as in Table 10, where convenience of printing has been considered.

The order of balance adopted is S, T, O, P, K, L, E, and F. The *K*-values for the two lowest floors are first inserted as column-end moments in Fig. 13, and rough estimates, which have been underlined, are made where necessary. (A dash has been placed where an estimate is not required.) Rough values for M_{TS} and M_{TU} are found by distributing $M_{TP} + M_{TX}$ approximately in the ratio of the stiffness (shown in brackets) of TS and TU. Joints S and T are then balanced (Table 10). The results of this balance help in estimating the moments necessary for the balance of joints O and P, remembering that values tend to fall off in upper floors. For example, since the first balance gave M_{TS} as +17.6, M_{TO} is taken as +17.0.

---

[26] *Bulletin No. 80*, Univ. of Illinois Eng. Experiment Station, p. 20.

[27] "Continuous Frames of Re-inforced Concrete," by Hardy Cross and N. D. Morgan, John Wiley & Sons, Inc., New York, N. Y., 1932, p. 230; and "Theory of Modern Steel Structures," by Linton E. Grinter, Macmillan, New York, N. Y., 1937, Vol. 2, p. 169.

Thus rough estimates and the first balance are made for each floor successively. Table 10 shows the balance for the four lowest stories and includes the values of M_{AB} and M_{BF}, which were obtained by balancing joints A and B.

The sum of the column-end moments for each story is now found, and, although the additions can be recorded in Fig. 13, they have been omitted to save printing. The column moments are altered to make their sum equal to the appropriate sidesway moments for half the truss, shown on the left of Fig. 13. Since, for the bottom floor, the sum of the moments is −72.5, they are increased in the ratio $\frac{84.8}{72.5}$. The values of $\frac{6\,E\,K\,\Delta}{L}$ for SW and TX are increased in the same ratio.

The new values of M_{TP} and M_{TX} are now −20.7 and −21.8. Their sum, −42.5, must be balanced by the beam moments M_{TS} and M_{TU}. Thus, the closest approximation presumably would be obtained by dividing 42.5 in the ratio of the last found values (as, for example, +17.6 and +20.8) of M_{TS} and M_{TU}, but great accuracy is not required, and a "round figure" adjustment to +20.0 and +22.5 is sufficient at this stage. All sidesway adjustments are shown in italics in Fig. 13.

A second balance and sidesway adjustment are now made with the result that values for moments and deflections are within about 5% of the "exact" values given by Messrs. Wilson and Maney.

It may be concluded that the method offered herein gives satisfactory results in the analysis of moments due to wind loading. Although the time taken may be a little longer than by some other methods, the reduction in arithmetical checking more than compensates for this. There is a fair amount of written work, because nearly all the calculations are recorded. However, this is an advantage rather than otherwise, since it facilitates the checking of the data. As the method involves the calculation of $\frac{6\,E\,K\,\Delta}{L}$ for each column, the final floor deflections can readily be computed if required.

Finally, the writer thanks all the contributors to the discussion and expresses his appreciation of the points raised. Some do not call for a detailed reply, and some were answered by other contributors. Time will show whether "moment balance" has any permanent value; if it has, future developments will be greatly helped by the discussion.

PERMEABILITY OF MUD MOUNTAIN DAM CORE MATERIAL

By Allen S. Cary,[1] Assoc. M. Am. Soc. C. E., and Boyd H. Walter,[2] and Howard T. Harstad,[3] Juniors, Am. Soc. C. E.

With Discussion by Messrs. F. H. Kellogg, J. E. Christiansen and Milton Fireman, William P. Creager, and Allen S. Cary, Boyd H. Walter, and Howard T. Harstad.

Synopsis

During the early investigation of the material contemplated for use in the impervious core of the Mud Mountain Dam (in a northwestern state), it was proved that the moisture content of the material when compacted had a much greater influence on the permeability than did the density of the material, within the range of densities at which it would be compacted during construction. Since the voids in the soil act as conduits for the water, it is postulated that the water content of the soil at the time of compaction governed the arrangement of the voids. At a high water content, the voids were apparently all of uniformly small size and the permeability was low. At a low water content, but at the same numerical void ratio or density, the voids were apparently of a wide range of sizes and the permeability was high. Thus, a wide or narrow range in void sizes may be likened to a wide or narrow range in particle sizes.

That the wide range or narrow range of void sizes may be imparted to the soil at will, with absolutely no variation in density being necessary, is proved by the extreme range in permeability among groups of samples compacted at very nearly identical densities but at different moisture contents.

This paper reports the results of an investigation inaugurated to determine the permeability-void ratio relationships of the proposed borrow-pit material as a basis for the distribution of the material in the various zones in the Mud Mountain Dam. So pronounced were the effects of slight moisture differences on the permeability of the material that moisture control during construction

became of paramount importance, not so much for the usual density control but primarily for control of the permeability of the core material.

Throughout the paper reference is made to "optimum water content" and "void ratio." In order to accommodate those who may not be conversant with this terminology, the following definitions are given:

> Optimum water content—"The water content at which the maximum density is produced in a soil by a specific amount of compaction."[4]
>
> Void ratio—"The ratio of the volume of intergranular space to the volume of solid particles in a given soil mass without regard to the proportions of liquid, air, or gas which may occupy the space."[4]

This paper will discuss in turn: (1) The material tested, (2) method and equipment, (3) test results, (4) interpretations, and (5) further investigation.

MATERIALS TESTED

Test results in this paper apply only to the materials used in the impervious core of the Mud Mountain Dam. The soil is a mixture of stream gravel and glacial till. The average mechanical analysis of the material after removing all boulders larger than 6 in. is shown in Fig. 1. Curves 1 and 2 represent 20% and 40% till admixture, respectively. The curves reveal an extreme range of particle sizes from colloids to 6 in.

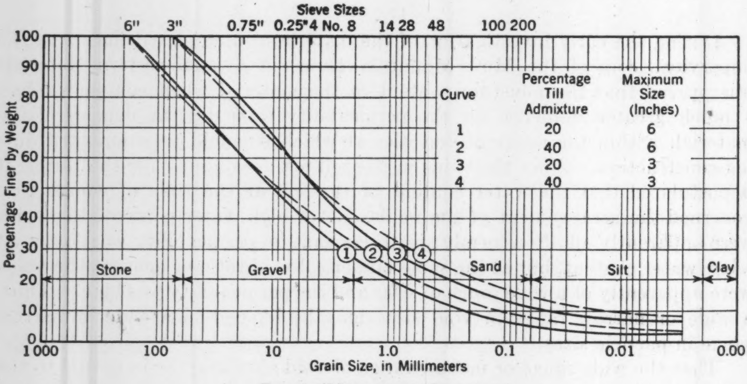

FIG. 1.—MECHANICAL ANALYSIS

The colloids are found primarily in the stream gravel and occur naturally as a coating around the particles in the deposit. They have been identified by the National Bureau of Standards by X ray and petrographic analysis as montmorillonite, an alteration product of volcanic glass and ash. Because of its extreme flatness, montmorillonite has been described as a "one-dimensional colloid." The extreme sensitivity of the mineral to excess moisture results in a marked loss of stability in the gravel when it is slightly above the optimum water content.

---

[4] "Soil Mechanics Nomenclature," *Manual of Engineering Practice No. 22*, Am. Soc. C. E., 1941.

For all permeability tests, samples containing only those particles passing a 3-in. screen were used. Mechanical analyses of this material are shown in Fig. 1, curves 3 and 4. The range of void ratios at which the material was tested was limited to those expected during ordinary construction on the fill.

EQUIPMENT AND METHODS

Apparatus.—Cylinders 13.54 in. in diameter and 12 in. high (1 cu ft) were used throughout the testing program for compaction and permeability. The permeameters were arranged with screens top and bottom to permit the free passage of water to and from the sample, and they were operated either as variable-head or constant-head upflow permeameters, as shown diagrammatically in Fig. 2. Except for very pervious materials, all tests were run with the variable-head hookup.

FIG. 2.—PART SECTION OF PERMEAMETERS

Compaction.—The material was compacted in the compaction cylinder or permeameter in three layers with seventy-five 12-in. free-fall blows per layer of a 25-lb hammer with a 3-in. diameter face. This gave compaction which was equivalent to that obtained when the material was compacted on the embankment. After each layer was compacted, the surface was completely scarified to break up any surface skin that might tend to reduce the permeability.

Water.—The water was distilled and preheated to above room temperature so that there was a falling temperature gradient through the sample during the entire run. This assisted in the removal of trapped air in the sample and hence in the prevention of air-locking.

An apparatus for de-airing water was assembled similar to that described elsewhere by G. E. Bertram.[5] It was impossible to obtain enough water to run all of the tests and, since preheating the water seemed as effective in this material, the de-airing was discontinued entirely.

Test Procedure.—A sample was compacted in the cylinder at the desired moisture content and loaded with 1 ton per sq ft. Water was started flowing up through the sample with a constant-head hookup as shown in Fig. 2. When the sample had become saturated, or rather when water appeared at the upper surface of the sample, the valves were turned for variable head, and duplicate permeability tests were run. For the long-time tests, the valves were turned back for constant head, and each 24 hr thereafter, for a period of from one to eight weeks, permeability determinations were made.

Tests and Test Results

The specified moisture limits on the embankment were within 1% above and 2% below the optimum moisture. To allow for factors of uncertainty in field control and to determine any dangerous or difficult conditions that might be approached at the upper and lower moisture limits, laboratory tests were run on the material ranging from 4% below the optimum water content to 4% above.

Tests were run on the materials in four groups, as follows: Gravel with (1) 20% till admixture, (2) 25% till admixture, (3) approximately 40% till admixture from a test fill, and (4) core material with approximately 35% till admixture, sampled during construction of the dam.

Group 1, 20% Till Admixture.—A cubic yard of the core material containing 20% glacial till and 80% gravel was thoroughly mixed, and by successive quartering was divided into eighteen "identical" samples of approximately 160 lb each. Three of the samples were used to determine the optimum water content of the material. On the basis of this determination, three of the samples were placed in the permeameter at 4% below the optimum, three at 2% below, three at the optimum, three at 2% above, and three at 4% above the optimum. Fig. 3 shows the results of compaction tests plus the unit weights obtained when compacting the material in the permeameters at the various water contents.

As each sample was placed in the permeameter, it was saturated and the permeability test run. All samples were placed as nearly as possible in the same manner except that the water content was varied. There was, of course, some unavoidable variation in the void ratio.

---

[5] **"An Experimental Investigation of Protective Filters," by G. E. Bertram, publications from the Graduate School of Engineering, Harvard Univ., Cambridge, Mass., Soil Mechanics Series No. 7, January, 1940.**

When permeability is plotted against void ratio, on semilogarithmic paper, a straight-line relationship is usually apparent for most soils. In group 1, however, there is none of the usual straight-line correlation between the permeability and the void ratio of the entire series, as shown in Fig. 4(*a*). However, there is a good correlation between each set of three points obtained from those samples placed at the same water content. Fig. 5(*a*) shows a definite correlation between the permeability and the water content at which the material was placed.

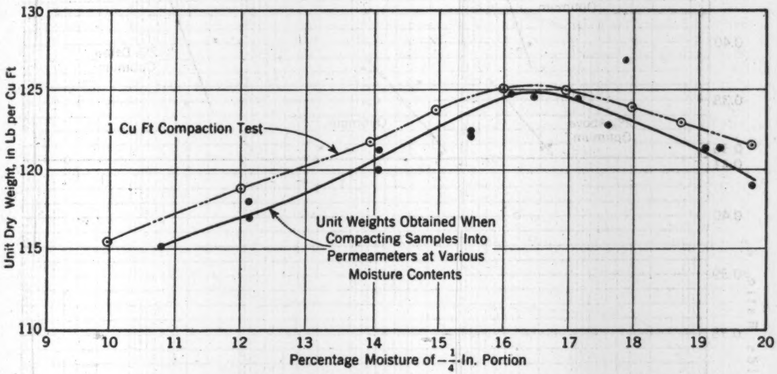

FIG. 3.—UNIT WEIGHT VERSUS MOISTURE CONTENT; 20% TILL ADMIXTURE

Group 2, 25% Till Admixture.—A similar series of tests was run for a 25% till admixture with the same permeability-moisture correlation as obtained in group 1. These tests are plotted, permeability versus water content, in Fig. 5(*b*). Permeability-void ratios are plotted in Fig. 4(*b*) and show none of the usual straight-line relationships.

Group 3, 40% Till Admixture.—A third series of tests was run using samples selected at random from a test fill constructed of core material with approximately 40% till admixture. The permeability-moisture correlation in Fig. 5(*c*) is better than might be expected when it is considered that this material varied considerably in till content and in mechanical analysis. Permeability-void ratios are plotted in Fig. 4(*c*) with the same complete absence of correlation.

Group 4, Embankment Material.—Fig. 6 shows the results of observations on 256 of the samples taken for permeability control of the core of the dam during the early part of construction, and directly from the borrow pit during excavation operations. The till admixture varied from 25% to 40%. All tests were run at the water content at which the samples were received in the laboratory. Here again, the permeability-moisture correlation was surprisingly favorable when it is considered that the mechanical analyses of the samples varied considerably.

It will be noted that, in both groups 3 and 4, there is a limited range of water contents. Had the range been wider, there is little doubt that the curves could be drawn as shown by the broken-line extension of the curve in Fig. 6.

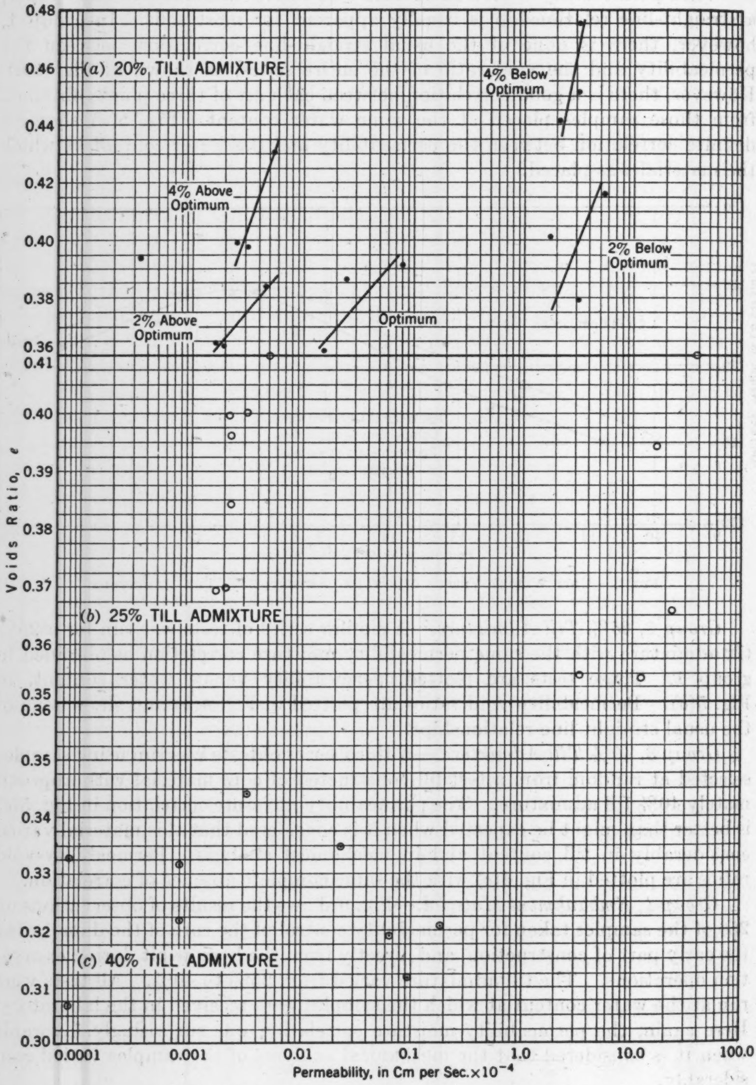

FIG. 4.—PERMEABILITY VERSUS VOID RATIO

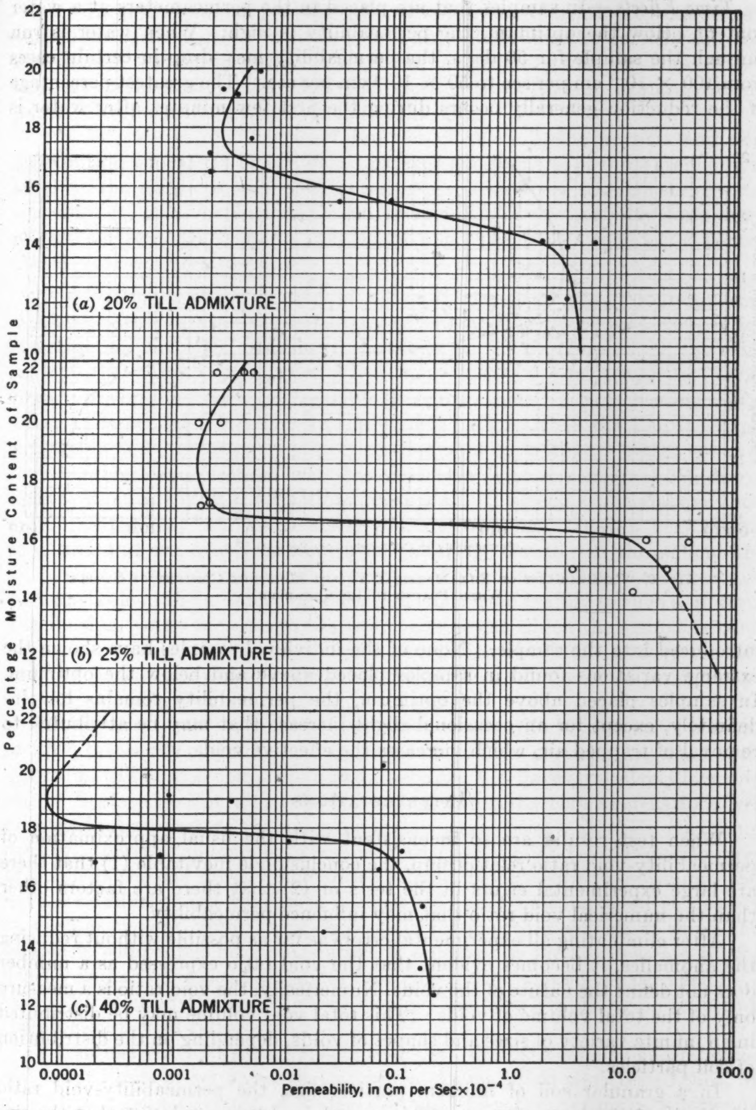

Fig. 5.—Permeability Versus Moisture Content of Sample When Placed in Permeameter

Time Effects.—In samples that are placed in the permeameters at a water content below the optimum, the permeability is high. When water is run through the sample for 56 days, the permeability may drop in certain cases from 100 × 10^{-4} cm per sec to 50 × 10^{-4} cm per sec. The greatest percentage of the reduction generally occurs during the first few minutes after water is introduced into the sample. None of the individual samples have shown the extreme variations found in samples placed above and below the optimum. In samples placed above the optimum, the permeability remains low indefinitely, except for an occasional slight increase that may be attributed to removal of trapped air, which increases the effective voids.

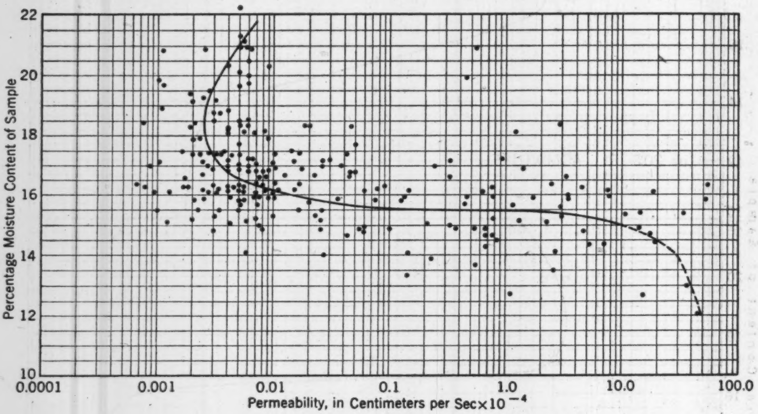

FIG. 6.—PERMEABILITY OF FILL MATERIAL VERSUS MOISTURE CONTENT OF SAMPLE WHEN PLACED IN PERMEAMETER

INTERPRETATIONS

When test results are so inconsistent with the usual approximation of permeability-void ratio relationship, the conclusion is inevitable (1) that there are large experimental errors in the tests or (2) that there are factors other than the numerical void ratio that may influence permeability.

After eliminating all experimental errors as far as possible without reducing the anomalies, it becomes evident that the void ratio expressed as a number does not define the nature of the voids. Numerically, the void ratio is a measure only of the total volume of voids. This total void volume may be distributed in an infinite variety of sizes and shapes of voids, depending on the distribution of soil particles.

In a granular soil of uniform particle size, the permeability-void ratio correlation is fairly consistent. This is explained by postulating that the size and distribution of the voids are more or less constant. In a well-graded soil with a small amount of clay included, consistent permeability-void ratio correlation can be obtained only when, and if, the particle and void distribution can be controlled. Control may be exercised under two conditions:

(1) In any given sample, the void ratio may be reduced progressively by consolidating the sample without appreciably disturbing the particle and void distribution. If permeability tests are run concurrently with the consolidation and the permeability-void ratio relationship is plotted on semilogarithmic paper, the plot will approximate a straight line.

(2) In a series of "identical" samples of the soil, the particle and void distribution appears to be controlled by exercising control of the water content at which the sample is compacted into the permeameter. At a constant water content but with varying void ratio, the results of permeability tests when plotted on semilogarithmic paper again approximate a straight-line permeability-void ratio relationship.

The optimum water content of a 1-cu-ft sample of Mud Mountain core material, with a maximum particle size of 3 in. as determined by a compaction investigation, is 11.5% of the dry weight of the entire sample. In the same sample, the water content of the fractions passing a ¼-in. screen is 16.5%. Now, if the optimum of a small sample using only those fractions passing a ¼-in. screen is determined, it is found to be 15.0%. Thus, when the 1-cu-ft sample containing the 3-in. maximum particle size is at its optimum water content, small aggregations of those fractions passing a ¼-in. screen are 1.5% above their optimum. With the fractions passing a ¼-in. screen slightly above their optimum, the clay, and particularly colloidal fractions, are in a very plastic condition and are relatively free to be uniformly distributed throughout the soil system during the compaction process. The montmorillonite clay becomes very unstable in the presence of water and lends itself readily to such a uniform distribution. Any increase in the water content at which the sample is compacted above this stage is reflected in a general increase in all voids in the soil, and the permeability-void ratio relationship then approaches a straight line (see Fig. 4), reflecting the numerical void ratio.

If this same sample were to be compacted into a cylinder at a water content of 1.5% below the optimum, the aggregations of finer particles will be at their optimum, will be well compacted, and, therefore, will have a relatively low void ratio. Surface tension and cohesion acting within the clay aggregations will be contributing factors in maintaining the aggregations at their maximum density, thereby enhancing a nonuniform particle and void distribution throughout the soil mass. The entire sample, being below its optimum, will have a relatively high void ratio because it cannot be compacted as densely as when at the optimum. Any decrease in the moisture content at which the sample is compacted below this stage is reflected in further decrease in the density and an increase in certain of the voids in the soil, and the permeability-void ratio relationship approaches a straight line (see Fig. 4), again reflecting the numerical void ratio.

The numerical void ratio appears to govern the permeability at the upper and lower limits of water content at which the materials were tested, but, at a relatively narrow range of water contents near the optimum, enormous changes of permeability take place with no change in void ratio necessary. This range of water content marks the transition from a condition of more or less uniform distribution of the fines on the wet side to a condition of concentration of fines into aggregations held together by cohesion and surface tension on the dry side. It is interesting to note that this range of moisture on either side of the optimum is almost the exact range originally specified for field control on Mud Mountain Dam.

Possible Application

In determining the permeability of certain pervious foundation materials, it is sometimes quite impossible to obtain undisturbed samples or to test the material in place, in which case it is common practice to determine the permeability of remolded samples over a range of void ratios. If this is done in conjunction with a single consolidation test, it has been suggested that the permeability-void ratio relationship should approach a straight line. However, if a series of tests is run on samples of the material compacted at various water contents, the results will indicate the degree of confidence that may be placed in the predictions of seepage through the foundation materials. If wide variations in permeability are obtained that cannot be attributed to void-ratio change, some other means of determining the permeability of the foundation materials is indicated.

The early practice of puddling cores in earth dams accomplished the same end as is attained by compacting this material at some moisture content slightly above the optimum. Puddling results in a uniform soil particle distribution, in a uniform void-distribution, and hence in a low permeability for that particular soil. The fact that, in the Mud Mountain core material, there is only 1.5% to 3% of clay, and in a puddled core there may be nearly 100% of clay, does not alter the fact that a high water content assists in a uniform particle distribution.

Further Investigations

The investigation has been limited thus far to a single material that is rather distinctive in its particle-size distribution. In this material, the effects of moisture are so extremely pronounced that they completely mask, over a certain range, all effects of numerical void-ratio change. Investigations of materials from four other sources, with a narrower range of particle sizes and no montmorillonite clay, are being conducted. It is indicated that the results will not reach the almost impossible extremes of the results obtained by using Mud Mountain borrow-pit material, but that herein may lie the answer to certain minor variations from the expected straight-line permeability versus void-ratio relationships.

Authority and Acknowledgment

The laboratory investigation that forms the subject of this paper was conducted in the U. S. Engineer Soils Laboratory, at Mud Mountain Dam, under the direction of Capt. J. D. Lang, Frank R. Preble, William E. Hoy, and Albert H. Rodes, successive resident engineers on the Mud Mountain Dam project. The writers wish to express their appreciation to the entire laboratory personnel for their critical and painstaking work in developing the testing methods and equipment, and for the interpretations as herein set forth. The constant interest and friendly criticism of A. E. Jaskar, Jun. Am. Soc. C. E., and H. E. Johnson deserve special mention. H. R. Cedergren, Jun. Am. Soc. C. E., of the Portland (Ore.) Division, U. S. Engineers, and Profs. R. G. Hennes, Assoc. M. Am. Soc. C. E., and J. Hoover Mackin of the University of Washington, at Seattle, have read the manuscript and offered a number of valuable suggestions.

DISCUSSION

F. H. Kellogg,[6] **M. Am. Soc. C. E.**—The fact that distribution of voids in a soil, rather than total voids volume, may be a diagnostic criterion of soil behavior has been excellently and strikingly demonstrated by the authors. The results of a number of permeability tests on several soil types are shown, in Fig. 7, to give results similar to those shown in Figs. 5 and 6. Such behavior is of practical significance in several ways, particularly in considering the swelling and softening of a compacted soil due to wetting.

Experience with fine soils compacted to form very hard, resistant masses, at moistures lower than optimum, has indicated that subsequent wetting of these masses results in a striking loss in strength. The wetting frequently causes considerable swelling. The same soils, compacted at moistures higher than optimum, show little or no swelling and softening after subsequent wetting. This has led to the control of moisture for such purposes as minimizing swelling of a highway subgrade under a concrete slab.[7] These effects of compacting moisture on swelling and softening, as actually observed, could be predicted, qualitatively at least, by test results such as those shown in Figs. 8 and 9. Fig. 8 shows, as points I, II, III, etc., the moistures and densities of a soil as compacted, and, as points 1, 2, 3, etc., the corresponding moistures and densities after wetting subsequent to compaction. Fig. 9(*a*) shows, as ordinates, the coefficients of internal friction of a soil that was submerged and saturated after being compacted at the moistures shown as abscissas; and Fig. 9(*b*) shows corresponding data for cohesion. These data, together with those presented by the authors, indicate the disadvantages of compacting fine soils at less than optimum moisture, due to the comparative ease with which water can find its way between hard lumps in the soil, softening them and weakening the entire mass. This was graphically illustrated by experiences with subgrades of A-5-7-type soils,[8] where time requirements and availability of materials prevented selection or special treatment of subgrade materials. Subgrades were either opened to traffic compaction or compacted at controlled moisture just before placing the 6-in. mechanically stabilized base and the asphaltic seal courses. After 2 to 4 months of predominately rainy weather, subgrade failures occurred at several places. At the points of failure, the subgrade had become wet and highly plastic. After checking for the effects of coarse aggregate and chemical changes in the clay, the following conclusions were made:

(1) Smooth, hard subgrades compacted at moistures lower than optimum were softened during wet weather to a plastic clay incapable of supporting the required wheel loads. This was true in spite of measures taken to promote drainage.

[7] *Engineering News-Record*, March 18, 1937, pp. 405–409.

[8] *Public Roads* 12, July, 1931, pp. 136–137.

(2) Subgrades compacted at moistures higher than optimum and immediately covered by the slab would not soften appreciably.

(3) Compacted clay subgrade could not be successfully plowed, moistened, and recompacted just prior to paving, as insufficient time for uniform distribution of moisture was available. Such a procedure merely served to wet the surface of the clay lumps, without affecting the compacted mass as a whole.

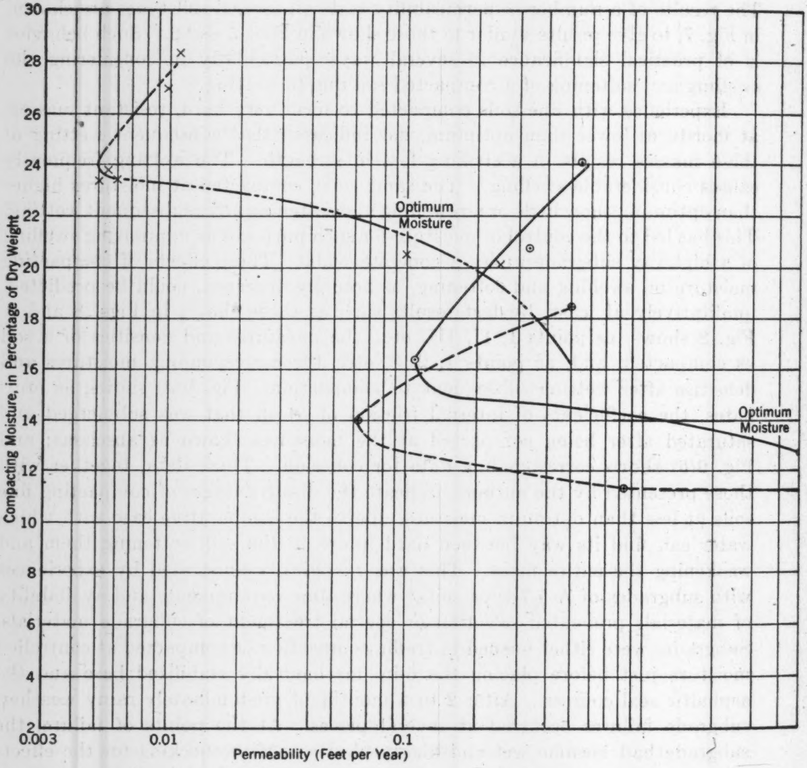

FIG. 7.—EFFECT, ON PERMEABILITY,

In the construction of certain impounding dikes, the relationships demonstrated by the authors have been used to advantage where only one type of material was available. At the upstream face of such a dike, high compacting moistures were used, giving a fill of low permeability. Downstream, lower compacting moistures gave a more pervious fill, increasing the effectiveness of the drains and partly offsetting the effects of anisotropy. Such a procedure, of course, must be consistent with the stability requirements of the dike, and the upstream fill must not be compacted when it is so wet as to cause cracking under wheel loads.

In the writer's experience, any soil that can be compacted at a given moisture to within 4 lb of the density which would permit no air voids at that moisture, and that has a soil mortar with an appreciable plasticity index, will deviate from the "normal" permeability-void ratio relationships. In other words, materials containing sufficient clay to form lumps at low moistures, and to lubricate coarse grains at high moistures, should fall into this class. Since montmorillonite is particularly sensitive to physicochemical changes, materials containing appreciable quantities of that mineral would require a lower percentage of fines to bring them into this class than would other materials.

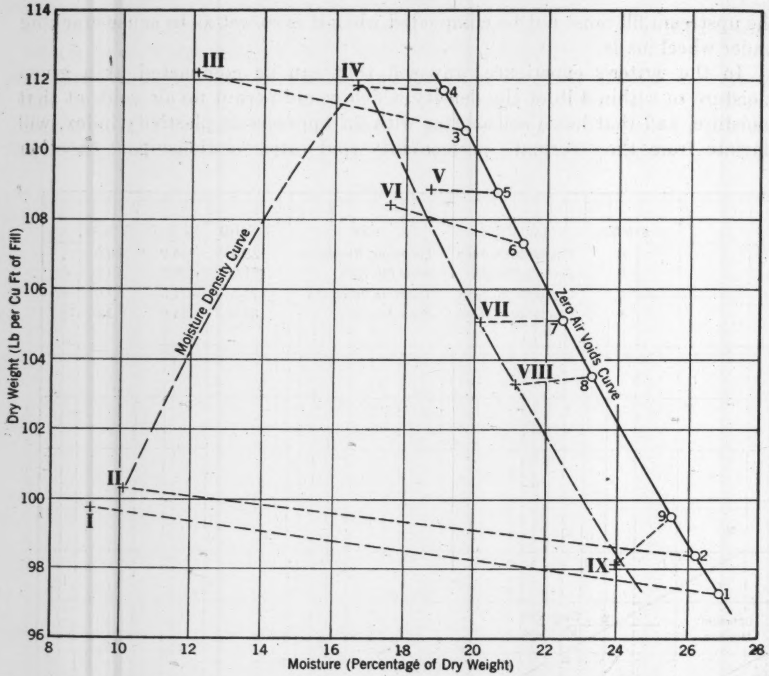

FIG. 8.—EFFECT OF COMPACTION ON VOLUME CHANGES DUE TO SUBSEQUENT WETTING UNDER LOAD OF 160 LB PER SQ FT (SOIL A-5 SILT LOAM, TENNESSEE RIVER FLOOD PLAIN, CHATTANOOGA, TENN.)

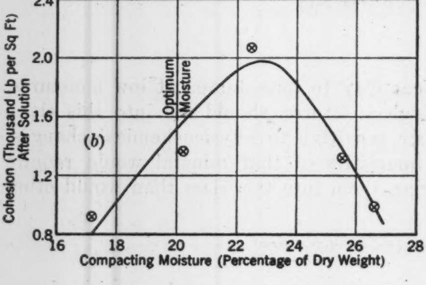

FIG. 9.—EFFECT OF COMPACTING MOISTURES ON FRICTION AND COHESION OF SATURATED SUBMERGED SOIL (SOIL A-5-7 IS A CLAY LOAM, WITH DOLOMITE RESIDUUM, FROM DANDRIDGE, TENN.)

J. E. Christiansen,[9] **Assoc. M. Am. Soc. C. E., and Milton Fireman,**[10] **Esq.**—Differences in permeability that can be obtained merely by varying the soil-moisture content at which the material is compacted are emphasized in this interesting paper. They reveal a phenomenon that probably has not received sufficient attention and about which very little has been reported in the literature on this subject. The tests reported show variations in permeability as high as 10,000 to 1, caused by differences of only 1% or 2% in soil-moisture content at the time of compaction in the permeameter.

It is the purpose of the writers to call attention to another factor, generally overlooked, that also can cause very large differences in permeability values of soils—namely, the chemical composition of the water used for the permeability test. The writers have been primarily interested in the permeabilities of agricultural soils as related to infiltration of rain and irrigation water and to soil drainage. In these studies, the soil in the permeameter has not been compacted highly, but has been brought approximately to the field density of the soil. It is possible that the large differences in the permeabilities of these soils, resulting from differences in quality of water, would be reduced greatly in magnitude if the materials were compacted more highly, but, as yet, no tests have been made to support this possibility.

In preparing the samples for testing, the soil is first air-dried and sieved, poured into the permeameter, leveled, and then jarred a specified number of times to bring the materials to a fairly uniform density. Next, the soils are slowly wetted from below until the soil mass is saturated and most of the air has been expelled. Finally, the water is admitted to the top of the soil column; it passes downward through the soil and is caught and measured in a graduated cylinder.

Distilled water was used in the studies reported by the authors. Some of the soils tested at the Regional Salinity Laboratory in Riverside, Calif., are several hundred times more permeable to local tap water (which contains about 280 ppm of mixed salts—that is, approximately 34 ppm calcium, 35 ppm sodium, 6 ppm magnesium, 16 ppm chloride, 36 ppm sulfate, and 153 ppm bicarbonate) than they are to distilled water, or to waters containing a high percentage of sodium salts. As is well known, the colloidal complex of most agricultural soils of the West is mainly calcium saturated; that is, calcium is the principal absorbed cation. In general, these soils are reasonably permeable to water and have a suitable physical condition for cultivation and crop production. When water containing a high percentage of sodium salts is passed through these soils, base exchange takes place. The sodium ions replace a large part of the absorbed calcium ions, and the soils may become deflocculated, sticky, jellylike, and much less permeable to water. When leached with high sodium water, some soils remain moderately permeable as long as the salt content is fairly high, because the presence of salt tends to keep the soil flocculated. If the salt solution is replaced by a water of considerably lower salt concentration, the soil will disperse immediately and become relatively impermeable.

---

[9] Irrig. and Drainage Engr., U. S. Regional Salinity Laboratory, Bureau of Plant Industry, Soils, and Agricultural Eng., Agricultural Research Administration, U. S. Dept. of Agriculture, Riverside, Calif.

[10] Junior Soil Scientist, U. S. Regional Salinity Laboratory, Bureau of Plant Industry, Soils, and Agricultural Eng., Agricultural Research Administration, U. S. Dept. of Agriculture, Riverside, Calif.

Characteristic permeability curves for two agricultural soils are shown in Fig. 10. The curves show the changes in permeability that occurred with the amount of water which passed through the soil. The Hesperia sandy loam is a surface soil from near Bakersfield, Calif., and the Imperial clay loam is from near El Centro, Calif. These soils are typical of many others tested in that they show marked differences in permeability to distilled water as compared with ordinary tap water, or with waters containing only a few hundred parts per million of calcium salts. It will be noted that the Hesperia soil is more permeable to a solution of sodium chloride than it is to distilled water. However, had this soil been subsequently leached with distilled water, it would have been practically impermeable. One soil tested was 35,000 times as permeable to a water containing 800 ppm of calcium chloride as to distilled water.

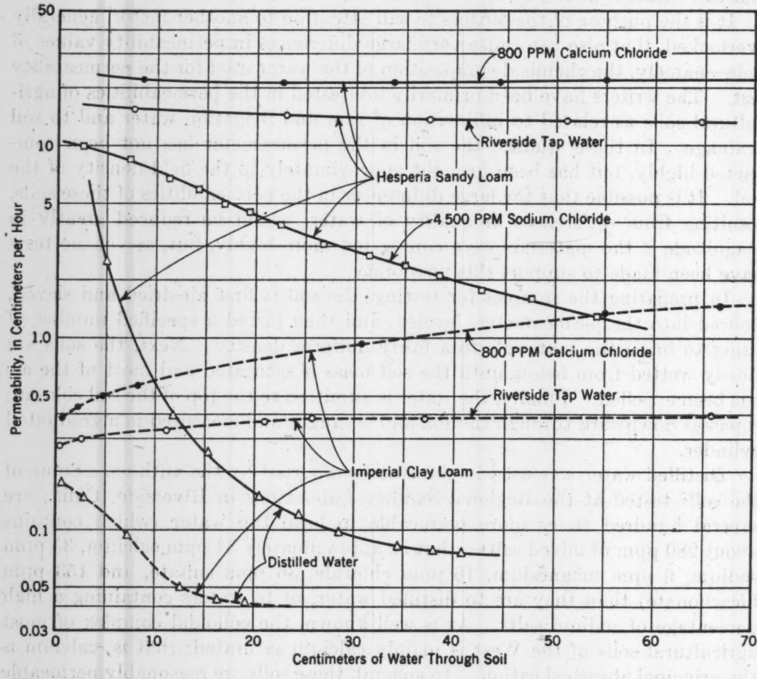

Fig. 10.—Permeabilities of Two Agricultural Soils as Influenced by Water Composition

Therefore, there may be a danger in using distilled water for testing the permeability of soils used for structural purposes. In place in a dam or other embankment, soils are subjected to the percolation of natural soil waters containing dissolved salts. They may be many times more permeable to these soil solutions than to distilled water.

William P. Creager,[11] **M. Am. Soc. C. E.**—For impervious materials an amount of moisture should be provided which is slightly greater, rather than slightly less, than optimum, particularly when natural moisture content is deficient and more must be added. This fact is indicated strikingly in this paper.

It is understood that the laboratory tests of the Mud Mountain Dam core material showed no tendency to swell when saturated subsequent to loading. Although the montmorillonitic fraction of the soil is subject to swelling, it constituted only about 1% of the total volume.

However, the following description of the expected behavior of a soil subject to swelling is so similar to that observed at Mud Mountain that it is felt that, although the Mud Mountain soil did not swell, there must have been some as yet undiscovered action allied to that produced by swelling. The following discussion applies to a soil subject to swelling.

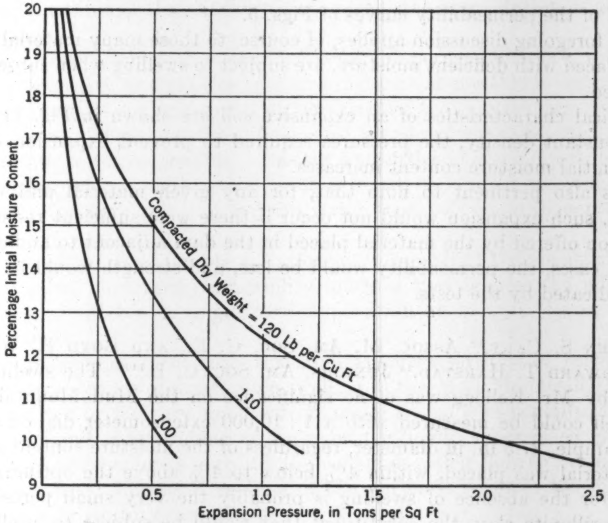

Fig. 11

It is interesting to trace the behavior of a soil swelling having different amounts of moisture when applied on the dam or in the laboratory: For a small amount of applied moisture, the applied moisture is not well distributed throughout the soil, the material is lumpy, and no amount of churning or compaction can distribute the moisture uniformly. Thus, a fraction of the material has too little, and another fraction too great, an amount of moisture. The fraction that has too little moisture may be subject to swelling when subsequently saturated, with resulting increase in voids and loss of strength.

---

[11] Cons. Engr., Buffalo, N. Y.

For instance, consider Fig. 3 with 16.5% of applied moisture. If one fraction of the material contains only 13.7% moisture and the other fraction 19.6% moisture and the total dry weight is 120 lb, the fraction containing only 13.7% moisture is subject to swelling, increased voids, greater permeability, and loss of strength.

However, if 19.6% of moisture were applied to the total mass, the dry weight still would be 120 lb, but the material would not be subject to swelling with consequent loss of desirable attributes. As the amount of moisture is increased, the distribution will be much more uniform; swelling and permeability have decreased and strength has increased.

When the moisture is increased to slightly greater than optimum, swelling has been practically eliminated, and the material has reached its optimum of density and strength after subsequent saturation, as shown by Fig. 5(*a*) for a 20% till admixture which has an optimum moisture of 16.5%. The use of an abundance of moisture, however, is obviously deleterious, as shown by the reversal of the permeability curves of Figs. 5.

The foregoing discussion applies, of course, to those many materials which, when placed with deficient moisture, are subject to swelling when subsequently saturated.

Typical characteristics of an expansive soil are shown in Fig. 11. Even for a constant density, the pressures required to prevent expansion decrease as the initial moisture content increases.

It is also pertinent to note that, for any given material and moisture content, such expansion would not occur if there were sufficient resistance to expansion offered by the material placed in the dam adjacent to and above it. In such cases, the permeability would be less, and strength would be greater, than indicated by the tests.

ALLEN S. CARY,[12] ASSOC. M. AM. SOC. C. E., AND BOYD H. WALTER,[13] AND HOWARD T. HARSTAD,[14] JUNIORS, AM. SOC. C. E.[14a]—The swelling mentioned by Mr. Kellogg was of no significance on the Mud Mountain Dam. No swell could be measured with a 1 : 10,000 extensometer dial on a 12-in.-thick sample, 27.5 in. in diameter, regardless of the moisture content at which the material was placed, within 4% below to 4% above the optimum. One reason for the absence of swelling is probably the very small percentage of montmorillonite clay, the constituent that would be subject to swell. Also, as stated in the paper (see heading, "Interpretations"), when the entire sample is at its optimum moisture content for maximum compaction, the finer fractions are considerably above their optimum. It may be surmised, then, that, with the entire sample 4% below its optimum, the fine fractions are near their optimum, at least nearly enough so that any swelling that does occur is so minute that it cannot be measured.

If the Mud Mountain core material were placed at some moisture content lower than optimum, there can be little doubt that subsequent wetting would lower the shearing resistance of the material appreciably. It could not be compacted to the maximum density at a low moisture, and thus the full shearing resistance of the material would not be mobilized. The slightly lower than maximum shearing resistance of the material when placed at a moisture above the optimum is an absolute minimum for the structure as a whole and will tend to increase as settlement and consolidation within the mass take place. However, the core serves no structural purpose in this particular dam; it merely acts as an impervious member held in place by the dumped rock shells.

[13] Aviation Cadet, U. S. Army, Los Angeles, Calif.

[14] Ensign, U. S. Coast Guard, Norfolk, Va.

The interesting discussion by Messrs. Christiansen and Fireman reveals another point that complicates further the determination of the permeability of a soil. As stated in the paper (see heading, "Equipment and Methods—Water"), distilled and de-aired water was used in the Mud Mountain Dam laboratory for the early part of the work but was discarded later in favor of heated distilled water. The heating was required to insure a falling temperature gradient through the soil sample to prevent the precipitation of air within the sample.

There are so many factors that influence the permeability of a soil that it is almost necessary to eliminate as many variables as possible in order to have a common basis of comparison for those variables that are inherent within the soil structure. Therefore, the influence of air, dissolved salts, etc., must be eliminated in so far as possible. Present knowledge of the subject forbids an unvarying procedure; rather, all variables must be studied individually and collectively for each soil and for the water that will come in contact with the soil.

In view of the considerable variation in permeability that is attributed to dissolved salts, no future permeability analysis that ignores the effects will be entirely applicable to a practical application as in dam, levee, or filter construction.

Mr. Creager has mentioned the swelling characteristics of certain soils. Probably the absence of measurable swelling in the Mud Mountain Dam core material is due to the very small percentage of the subject constituent. It is entirely probable that swelling of the montmorillonite takes place, partly, at least, in such a direction as to reduce the void sizes rather than to cause swelling of the soil mass. The total swelling of the soil mass becomes too minute to measure in a laboratory sample.

Apparently it was not clearly stated in the paper that the moisture content of the tested samples was reduced as little as possible below that at which the samples were to be tested. This precaution was taken to reduce the nonuniform moisture distribution in the soil mass.

RESISTANCE OF SOFT FILL TO STATIC WHEEL LOADS

By W. Watters Pagon,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Jacob Feld, and W. Watters Pagon.

Synopsis

The mathematics of stress in an elastic body, under a load system applied at the surface of the body, is outlined in this paper. The principles are applied to the construction of airplane runways upon a plastic mud fill, to resist airplane wheel loads and to control the placing of granular fill upon the mud. Finally, the paper shows the practical application of the mathematics to the construction of the landing field of the Baltimore (Md.) Municipal Airport.

Historic Background of the Problem

A general history of the Municipal Airport in Baltimore was presented by the writer in 1940, giving in some detail the character of the mud that was pumped into the site as a base for the construction of a landing field, and how this mud fill was allowed to stand for a long period of years before it could be used.[2] Tests indicative of the character of the mud are given in this reference.

At the beginning of the work described herein, about 12,000,000 cu yd of mud, and about 4,000,000 cu yd of granular fill, had been placed by contract. About 400,000 cu yd of the total fill remained to be placed. The granular fill had been hauled by large capacity trucks, either from a distant borrow pit or from barges loaded with dredged material which were moored to the airport bulkheads. It had been placed in the manner most convenient to trucking and, therefore, much of it was in the form of long "fingers" extending into mud areas, the fingers having a depth such that they had been able to support the weight of the heavy trucks.

When it was decided to abandon this method of construction, post-hole auger borings were made on 5-ft centers each way throughout the area of the four landing strips to determine how much granular fill had been placed on the

FIG. 1.—DEPTH OF GRANULAR FILL AT THE BEGINNING OF THE WORK

mud along these strips. The depth of fill thus found is shown by the contours in Fig. 1, the 0 contour representing the edge of all areas in which mud was exposed to the view, and the space between the 0 and 4-ft contours representing the areas in which there was less than 4 ft of granular cover. Outside of the 4-ft contour the depth of granular fill varied from 4 ft to more than the 8-ft length of the augers.

Later it was discovered that Fig. 1 is not completely correct. Before the previous contract work was discontinued certain mud areas above airport grades had to be lowered by the use of drag scoops. This grading exposed mud areas that were shallow and that overlay granular fill, or even areas in which the materials were sandwiched together. Nevertheless, Fig. 1 is substantially correct.

In such areas where the mud had bulged above airport grades and had been "decapitated," the consistency was soft, with 12 in. to 18 in. of dried crust, which had formed within a period of about eighteen months. Fig. 2 is a view of such an area. (The cracks shown in the foreground, although similar to the shrinkage cracks of the mud fill, are in a thin layer of mud washed into puddles of rain water and dried in the sun.) Where the old crust had not been disturbed its thickness was greater. Where the mud was near the surface, but covered with a shallow granular fill, there was a firmer crust. Again, the areas at the south side of the airport had much firmer mud than the areas near the north corner, because the discharge line from the dredge which had pumped in the mud about 1928 had been near the south boundary line, and all of the coarser materials had settled out here, leaving the finest materials to progress slowly to the north corner.

Where mud and granular fill are mixed in proper proportions the binding power of the mud produces a very firm product. For example, where mud drippings from trucks (which were hauling it to the disposal areas) became intimately mixed with the granular fill, a wearing surface was formed which had a remarkably high strength in dry weather. Even in long-continued wet weather only the surface became soft and slick. Again, where fingers of granular fill were quite close together, the mud between had often become much like soft rubber, through which a spade cuts as through cheese.

THE PLASTIC MUD

A "plastic" will be defined herein as a material which is: Perfectly elastic for stresses below some given value, but which is a viscous fluid for stresses in excess of that value. The problem at the Baltimore airport, therefore, involves two phases: (1) The last phase—a completed runway system, constructed of granular fill bearing upon the mud, stabilized at its surface, and sufficient to support airplane wheel loads and to prevent raveling; and (2) the earlier phase, in which it was necessary to superpose the granular fill upon the mud.

THE PROBLEM PRESENTED

The construction problem consisted merely of removing the least quantity of mud, and placing a minimum quantity of granular fill—that is, securing a maximum of uniformity in the depth of fill. The depth of fill must be sufficient to prevent weaving of the runway surface under the airplane loads specified by the Civil Aeronautics Administration; the character of fill must be satisfactory for asphalt stabilization because the entire field will slowly settle with time as the water leaves the underlying mud, causing any overlying concrete pavement to break. As far as possible, the material used for fill must be sharp and gritty so as to have a maximum of interlocking capacity and a minimum of capillarity.

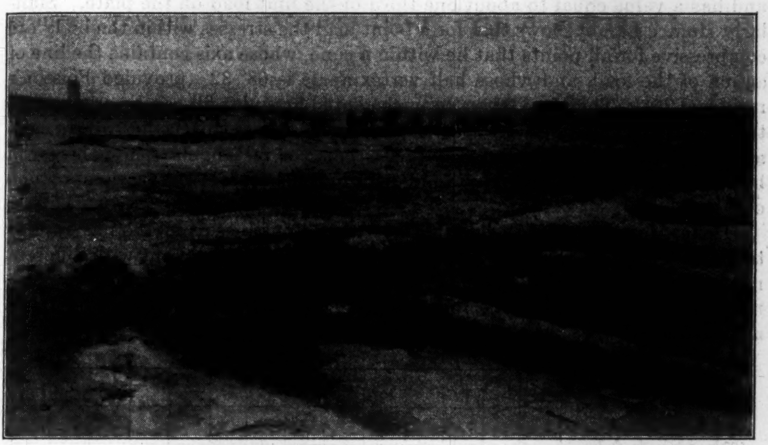

FIG. 2.—CHARACTERISTIC VIEW OF EXCAVATED MUD AREA

The purpose of this paper is to describe the method of determining how great a depth of granular fill should be placed upon the mud, how this fill should be placed, and how the mud should be, and was, removed.

STRESS IN A BODY PRODUCED BY A POINT SOURCE AT ITS SURFACE

The curves of Boussinesq's formula

$$s_z = \frac{3\,P\,z^3}{2\,\pi\,R^5} \qquad (1)$$

are shown in Fig. 3, in which s_z is the stress at various depths z below the ground surface and distances R from the point of application of the load P (r in Fig. 3 is the horizontal component of R). For a depth of 24 in. the stress is about one fourth of that for a 12-in. depth, but for a 36-in. depth it is again more than halved. Of course this theory presupposes a strictly elastic body throughout, whereas the airport consists of a granular and earthy fill overlying elastic mud. Experience has shown that the theory is a good approximation for earth materials, but there is no theory and no experience for the case in which the earth materials are superposed upon a mass of mud. It is fair to assume that so long as the mud is not overstressed, it can be considered an elastic support under a stratum of material that will be pseudo-elastic, or at least capable of transmitting load through a cone of material. That earth materials can so transmit load was demonstrated at The Pennsylvania State College at State College, Pa.[3]

It can be shown that for a load applied uniformly over a circular plate the maximum shear occurs at a depth about equal to one third of the plate diameter, and has a value equal to about one third of the unit load on the plate. Similarly Horace Lamb[4] shows that for a point load the stresses within the body are compressive for all points that lie within a cone, whose axis contains the line of action of the load, and whose half vertex angle is 68° 32′ (provided Poisson's ratio is 0.25). Therefore, even an uncemented granular fill can be assumed to transmit vertical load to any area, at any depth, whose surface lies within such a cone. For a load distributed over a circular or rectangular plate there will be a frustum of a cone or pyramid within which there will be compression only.

Hence, for want of a theory that expresses Boussinesq's method as applied to a composite body having two layers, each perfectly elastic but with different moduli of elasticity, it becomes necessary to use the cone-of-compressed-material concept, and in the following the half vertex angle has been taken as 60°.

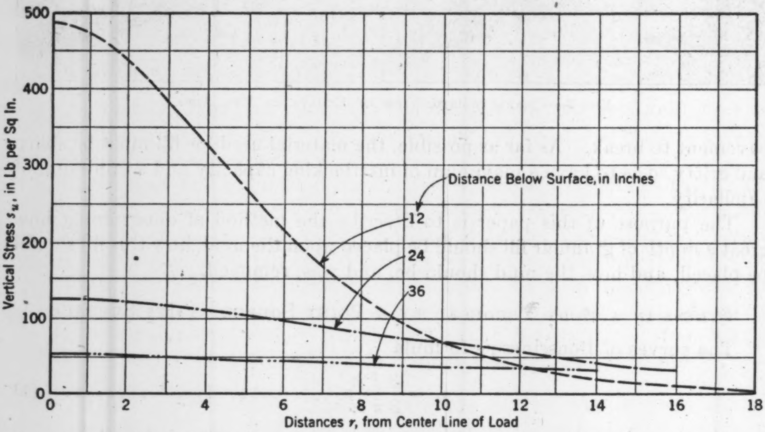

FIG. 3.—CURVES OF THE BOUSSINESQ FORMULA FOR A THOUSAND-POUND LOAD

If the computation is based upon an airplane wheel concentration of P = 50,000 lb, there immediately arises the question of contact area between tire and paving. At present it is true that the maximum tire pressure is about 65 lb per sq in., and to allow for further development 75 lb per sq in. will be used. This means that such a wheel concentration would require 667 sq in. of contact surface—that is, a circle of 29-in. diameter, or an ellipse of 24 by 36 in., etc. Bomber B-19 is reported to have a wheel load of 82,000 lb on a tire-imprint area of 1,000 sq in.[5] In order not to exceed a safe basis of computation, a diameter of 36 in. will be used which, for a depth of granular fill of 3 ft, and a half angle of 60°, would load an area of 13.4-ft diameter, or 140 sq ft; and, for a depth of 4 ft, an area of 225 sq ft. The respective uniform unit loads on the mud surface, for $P = 50{,}000$ lb, would then be 360 lb per sq ft, and 225 lb per sq ft.

---

[3] "Experiments on the Distribution of Vertical Pressure in Earth," by R. B. Fehr, *Bulletin No. 11*, The Pennsylvania State College, State College, Pa., 1919, p. 118.

[4] "Hydrodynamics," by Horace Lamb, University Press, Cambridge, 1925, pp. 188–189; also "A Treatise on the Mathematical Theory of Elasticity," by Augustus Edward Hough Love, University Press, Cambridge, 2d Ed., 1906, p. 189.

Using the load of 225 lb per sq ft on the surface of the mud crust, and neglecting any value in the mud crust, the maximum shear, from the foregoing statement, would be about 70 lb per sq ft, and would occur beneath the center of the wheel concentration and at a depth of one or more feet below the mud crust. This might place the highest shear stress in the semiliquid mud; hence it becomes necessary to determine whether the mud can carry a shear of 70 lb.

If the shear exceeds the shearing resistance of the mud, movement will occur until the material flows sufficiently to reduce the maximum stress.

VISCOSITY TEST

To determine roughly what shearing strength the mud possessed, a test was made by screwing a duckpin ball to a galvanized pipe and loading the affair.

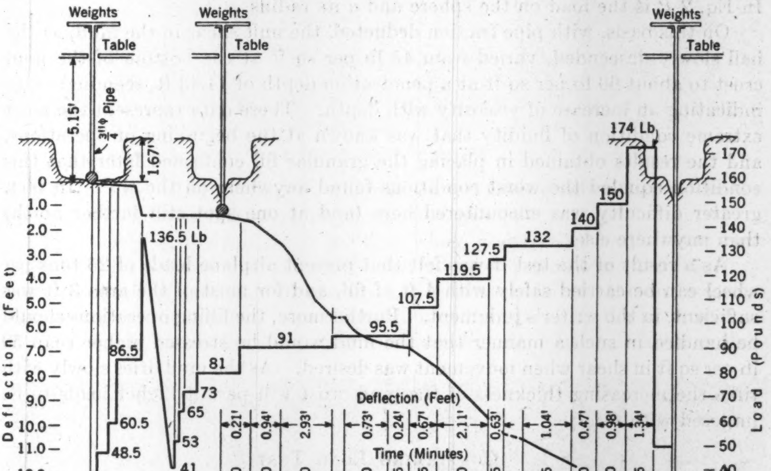

FIG. 4.—MUD VISCOSITY TEST, BALTIMORE MUNICIPAL AIRPORT, OCTOBER 20, 1939

Fig. 4 shows the curve of this test, with deflections, loading, time, and average velocities of descent. The test could not be entirely continuous, because twice it was necessary to add lengths of pipe, which involved removing the load. The ball had a diameter of $4\frac{1}{2}$ in. The site chosen at point X, Fig. 1, was an area in which the mud had been decapitated with a drag scoop about 18 months previously, and had then dried in the sun as shown in Fig. 2. The test was started at a depth of about 1.67 ft below the surface, which was where the mud was close to the plastic limit. It was impossible to know what friction was developed on the pipe, but the mud tended to develop a water film on the pipe as it closed in behind the ball, whose frictional resistance would be very small. Therefore, a friction force of 20 lb per sq ft of pipe surface was assumed.

---

[5] *Construction Series No. 59*, The Asphalt Inst., p. 5.

In the deflection range from 2.67 to 5.60 ft, the coefficient of viscosity is about 3,400; from 6.98 to 10.39, about 6,300; from 10.60 to 13.09, 9,700; and from 13.09 to 14.43, 5,900 $\left(\text{units are } \frac{\text{pounds} \times \text{seconds}}{\text{feet}^2}\right)$. If a greater value is given to the pipe friction, these results would differ accordingly. The maximum unit shearing stress on a sphere moving through a viscous liquid is 0.25 p, in which

$$p = \frac{P}{\pi a^2} \qquad (2)$$

In Eq. 2 P is the load on the sphere and a its radius.

On this basis, with pipe friction deducted, the unit shear in the mud, as the ball slowly descended, varied from 45 lb per sq ft at the bottom of the mud crust to about 60 lb per sq ft at a penetration depth of 14.43 ft, seemingly also indicating an increase of viscosity with depth. These data represent the most extreme condition of fluidity that was known at the beginning of operations, and the results obtained in placing the granular fill confirmed later that this condition equaled the worst conditions found anywhere on the site. In fact, greater difficulty was encountered here (and at one spot still farther north) than anywhere else.

As a result of the test it was felt that present airplane loads of 25 tons per wheel can be carried safely with 4 ft of fill, and for most of the area 3 ft was sufficient, in the writer's judgment. Furthermore, the filling operations should be handled in such a manner that the mud would be stressed higher than 50 lb per sq ft in shear when movement was desired. As the mud dries slowly with time the increasing thickness of the mud crust will permit higher loads to be imposed with safety.

Confirming Load Test

As a practical check on the mathematics, a load test was instituted. A truck was obtained of the low-body type used for hauling large equipment. Its weight was 11,275 lb on two rear axles, each axle being equipped with a pair of dual wheels, and a load of 5,500 lb on the front axle, equipped with two wheels. The wheel base of the rear end is 4 ft 3 in. between axles, and the front axle is 15 ft 10 in. from the forward rear axle. The truck body is 8 ft wide. The rear dual wheels are 12 in. apart, with 5 ft between centers of inner wheels. All wheels are equipped with 9.75 by 20 pneumatic tires. This truck was loaded with 17 tons of pig lead (see Fig. 5), making a total rear-end load of 22.6 tons. Allowing for tire compression the 22.6 tons were applied on two areas, each about 2 ft by 5 ft or somewhat more, one surrounding each set of four wheels. On actual airplanes having loads comparable to these, the load wheels are from 18 to 22 ft apart, whereas the two areas combined approximate, roughly, the load on one single airplane wheel group.

FIG. 5.—TEST TRUCK LOADED WITH SEVENTEEN TONS OF PIG LEAD

This truck was driven about the field where granular fill had already been placed. The most severe condition occurred at one spot where borings indicated a depth of granular fill of only 1.9 ft measured from the surface, and actually several inches less from the bottom of the rut which the tires made in the soft, loose, untreated airport surface (see Fig. 6). In some areas a bulldozer was required to increase the tractive effort. The truck was left in such a position for 24 hr, and showed a settlement of about $\frac{3}{8}$ in. Again at various spots a 47-ton caterpillar crane on a wood mat was operated continuously upon fresh fills of 4-ft depth. When in operation the crane would jar the mud, and

FIG. 6.—RUTS FORMED IN THE SOFT SURFACE OF THE GRANULAR FILL

slowly settle, so that every hour or so it was necessary to back it off and place more fill, and then to move it forward for a further reach. The mud clearly is "thixotropic"—that is, it becomes less viscous and more fluid when jarred, but regains its viscosity when allowed to be quiet. The truck-hauling roads also "held up" with a depth of about 4 ft, although in the softest areas there was slow and continuous settlement.

STRESSES DURING CONSTRUCTION OF THE GRANULAR BLANKET

In 1912 S. D. Carothers[6] derived a method of computing stresses within an elastic body when subjected, not to point loads, but to uniform, or uniformly varying, loads, having application only to two-dimensional problems. By assuming certain plane harmonic functions, or combinations of functions, he derived the stress and strain, for example, for a load having a triangular cross section, beginning with zero load along a straight line, and increasing linearly at right angles to this line. If, at a distance a, a reverse load of equal amount is then applied, there results a load condition which represents a uniform fill bounded on one edge by a sloping berm. For instance, this would represent the condition of the airport under a uniform fill advancing across the field with a straight front edge and having a slope along the front edge (see Fig. 7). By other modifications he obtained the stress condition for an infinitely long prismatic load—as, for example, a highway or railroad fill.

The writer converted this principle to derive the stress condition when a trench of infinite length is opened through the dried mud crust (see Fig. 8). He then amplified this theory by superposing a triangular prism along one or both edges of the trench as shown in Fig. 9. Since shear stress is the condition sought, the shear for different types of loading was computed, and is shown in Fig. 9 in a section at right angles to such loadings, with a sloping berm, having a horizontal width, a, the depth of fill being h, and the weight of fill $w\,h$, or p, per square foot. The drawings are dimensionless; that is, they are proportional throughout to the length a. It will be seen that the shear is maximum, for the blanket, under the middle of the slope, and at a depth of about 3.5 a, with a value of 0.318 $w\,h$. For other relations between the width of side slopes and the width of the trench, the numerical results would change slightly. The maximum shear occurs at a depth approximately equal to a and has a value varying from 0.31 p to 0.35 p. Fig. 10 represents half of the width of a runway, having a crown equal to h, bordered by a trench as shown.

Fig. 11 represents the program that was established for the construction of the runway fills through the soft mud areas. The initial condition is shown in Fig. 11(a), and the final condition in Fig. 11(g). The runway is crowned, and at each edge there is a perforated drain. The depth of granular fill is 4 ft, as is the minimum depth of each lateral drain. Fig. 11(b) indicates the mud area that is subject to motion for the condition shown. The intent was to construct, first, a hauling road down the center of the runway, noted as Fill 2, with (if possible) a hand-placed fill, marked Fill 1, placed previously. As Fill 2 settled under the vibration of the trucks hauling in the material, and dumping

FIG. 11.—PROCEDURE FOR BLEEDING SOFT MUD FROM BENEATH 500-FT LANDING STRIPS

fill beneath it. Only the width of the runway is shown in Fig. 11, but the procedure is the same for the 175-ft (or 150-ft) strips on either side of the runway width. The same description applies to all of the fills up to Fill 7.

To place lateral drains at each edge of the paved runway in the soft mud was impossible, except at great expense for piling. Moreover, there would be no certainty that the drains would remain where they were placed. Hence Fills 7 were designed to extend much deeper, and to pass entirely by the site of the sewer. When they were completed the sewer would then be constructed in an open trench dug into Fills 7.

There was an important additional concept, however, in the trench shown on each side of the runway, outside of the sewers. These trenches, known as "bleeding trenches," were planned as the line along which mud would be excavated. As the crust would be cut near the same line for the sewers anyhow, two purposes were served at the same time, and the strength of a considerable area of crust thus conserved.

The job was begun as planned, manned almost entirely with hand labor and trucks. The lateral trenches were opened, and the granular fill was brought in along the center line. Where the mud was too stiff to flow into the trenches, triangular fills were placed alongside the trench, so as to squeeze the mud out into it. Of course, there were many spots where the "fingers" of fill placed in the previous operations cut the mud areas so materially that it was necessary to adapt the scheme to local areas. This was done merely by treating an area as a circle, or as several circles, and by excavating the mud from the center and allowing the marginal fill to sink, which it did in the form of a large crater.

The landing strips have a width of 500 ft, but only the central 150 ft (200 ft for one runway) is paved and underdrained. The treatment of the 175-ft strips outside of the paving was the same, there being an outer trench along the edges of the 500-ft landing strip.

This theory (which is developed from Mr. Carothers' system[6]) is not a theory of viscous flow, but of static stress in shear. Until the test value of 50, 75, or 100 lb per sq ft shearing stress at failure is passed, the mud acts as an elastic body; after this stress has been exceeded, the mud acts as a viscous fluid. Therefore, the criterion is the shearing stress at the weakest point under each load condition. The criterion is indicated by the curves of unit shearing stress. One of the actual trenches is shown in Fig. 12.

After flow begins the mathematics is complex. In many cases the condition can best be described under the caption "isostasy." The granular fill, plus its contained rain water, plus the mud beneath, must balance the mud alone in the adjoining areas—having in mind, of course, that there is not exact equality of balance, because viscosity aids unbalance. The result of placing a fill upon an elastic membrane which covers and contains the mud (assumed to be perfectly fluid) is shown in Fig. 13, in which

$$j = \sqrt[4]{\frac{3\,w_2}{E\,h^3}} \qquad \text{(3)}$$

In Eq. 3, E = modulus of elasticity, w_2 = unit weight of mud, and h = depth of granular fill. When w_2 = 80 lb per cu ft and E = 300,000 lb per sq ft, x_0 for depths of 1, 2, 3, and 4 ft, respectively, is:

h (ft)	x_0 (ft)
1	14
2	24
3	32
4	40

This form of mud wave is quite similar to the waves that actually have developed on the field. It is clear that the shear is a maximum at the edge of the fill. Of course, the dried mud crust cannot be considered a perfect membrane.

However, it seldom happened that the crust sheared, so that in effect the crust did form a membrane. At the north corner of the airport the runway grade is 3 ft above the field, and, because of this inclination of the crust as the fill advanced, there were some places where the crust was forced forward until it reached solid fill, when it would at times be forced up over this fill like ice on a lake shore. This was corrected by filling uphill instead of downhill.

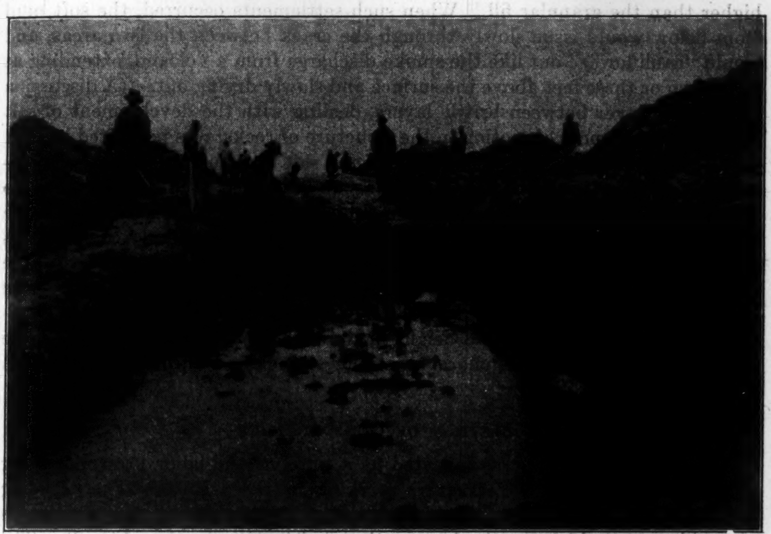

FIG. 12.—ONE OF THE BLEEDING TRENCHES AFTER A PERIOD OF RAINY WEATHER

In the area near where the ball test was made the mud did not behave as well as elsewhere. Through lack of foresight, and due to the fact that the fill occurred only along one side of the runway, the hauling road was held too long at one site, with several fills made upon it in order to maintain grade. The result was that after a heavy rain storm a considerable waterlogged area sheared

down past the near-by fills and sank a foot or more. It later became stable. At another point, very close to the south side of the field (where the mud in general was stiffest), there was an area of somewhat similar character in which the granular fill subsided, and the mud near-by rose until it stood perhaps 5 ft higher than the granular fill. When such settlements occurred, the soft mud from below would issue slowly through the crack between the two areas, and would "cauliflower" out like the smoke discharge from a volcano, extending at times two or three feet above the surface and slowly drying out. (A discussion of a plastic layer between brittle layers, dealing with the development of salt domes and evidences of motion in the structure of rocks, was presented in 1931 by A. Nadai.[7] For example, the flow of the salt layer under the superincumbent layer of rock is described, and its accumulation at points of weakness to form domes. Photographs of models demonstrate the flow of lava through the throat of a volcano; and they also show slip lines where the plastic materials have sheared on either side of the throat as well as flow lines indicating the character of flow into and up through the throat. At the lower end of the throat the slip lines converge, and the flow lines indicate a sort of "vena contracta," which disappears at a height in the throat of roughly three times the throat diameter, such as is characteristic of viscous flow through a tube, with slip at the walls.)

METHOD OF CONSTRUCTION

As stated, the work was initiated as a purely hand-labor project, having about 1,000 laborers and truckers working in three shifts. The bleeding trenches were first opened up through the mud crust, using runway boards alongside upon which to wheel away the mud in barrows (see Fig. 2). The mud was sticky, which made it difficult to disengage it from the shovel unless a pail of water was handy. The men had to stand on planking. Each day the trench would be excavated to a depth of from 12 in. to 24 in.; each night it would fill up again to within about 6 in. to 12 in. of the surface, the cross section of the surface of the mud as it oozed up being approximately a parabola. On the basis of an unbalance of one foot between the trench bottom and the adjacent mud, and a shear stress amounting to 0.3 $w\,h$, the mud here had a shearing strength of about 30 lb per sq ft, the site having been selected in the area of softest mud. There were many small areas (as shown in Fig. 1) which were bled locally.

The plan of the work is shown in part by Fig. 14 on which is a part of the northwest-southeast runway. The trench layout and the location of the triangular loading fills are shown clearly, as also are the boring depths to the mud beneath the granular fill of the original contract. In the northerly part of this runway the method was successful, but near the southerly end it was soon found that the mud was of almost cheesy consistency and required excavation by means of a clamshell bucket.

The hand-labor method, however, proved to be too slow, and progress was delayed. This was aggravated by the fact that the work was begun in De-

cember, 1939, and the weather throughout the winter was very cold, so that efficient work was impossible. When the engineers decided that the use of cranes would be necessary, the method required modification.

With cranes it was no longer possible to bleed out the mud from the half width of the runway, because the crane booms could not reach sufficiently far. Again it was unnecessary to use the triangular loading fills mentioned previously, because, in a sense, the crane itself, and the trucks serving it, constituted such a fill, and because of excessive vibration. It was desired as far as possible to preserve the dried crust, but a continuous strip operation could not be adhered to everywhere; and in lieu of the continuous strip, a local treatment was adopted. This consisted in forming a loading fill around small cells, by pushing the fill out with bulldozers to form a pocket, and then bleeding the mud out with the crane from a central point of the cell which was within reach of the boom. The net effect of this practice is that the granular fill was placed to reasonably uniform depths, but at the center of each pocket or cell the fill finally closed in upon the surface of liquid mud and not upon dried crust, which means that each such cell will dry more rapidly at its center. In other words, it will dry more rapidly at the point or points from which the mud was bled, and the runway paving, therefore, will develop a sag at each such spot. The principle behind the continuous trench method, as already explained, was to preserve the dried crust over the entire area of the runway paving excepting the narrow strip adjacent to the lateral drains, where no method of construction would preserve the crust.

Lest the impression be gained that the trench method, or the cell method, could have produced a paved area that would settle with perfect uniformity, the writer emphasizes that only in the areas where the mud was exposed over a relatively long distance could the trench method produce uniformity, and there were several such areas having lengths of 500 ft and more. Inspection of Figs. 1 and 14, however, will show that the previous filling operation had left the field in such condition that a large percentage of the area of the runways required local treatments.

FUTURE SETTLEMENT

A most pertinent question must already have formed in the reader's mind—namely, Why should the City of Baltimore undertake to construct an airport upon such a fill? The question was answered by the two consulting engineers employed in Stage Two.[8] The first reason was that the airport had been constructed far beyond the pierhead line of Baltimore Harbor, under a revocable permit of the federal government, and if not used as an airport it was subject to such a "cloud" on the title that it would be unsalable; the second reason was that the city had $3,000,000 invested in it at the time of the engineers' report. Another and more excellent reason was that this site is one of the finest on the Atlantic Coast for a seaplane base, and under the law the landplane base and seaplane base must be contiguous. For such reasons the city was forced to complete the airport, regardless of the character of the mud that had been pumped in.

---

[8] *Transactions*, Am. Soc. C. E., Vol. 106 (1941), p. 1342.

The consulting engineers stated that the fill would settle for years to come. The mud surface has performed as was predicted, because there was a settlement of the surface of from 2 to 3 ft (in a depth of about 25 ft) in ten years. However, the rate of settlement slows rapidly as the upper part of the mud dries, because the rate of percolation of the water to the surface where it can dry out in the sun is extremely slow, due to the fineness of the mud particles.

Where the dried crust was undisturbed in the operation, the settlement will be slow, for this reason, although it will continue for a long period; where the dried crust was removed, and the granular fill placed upon fresh soft mud, the settlement will be greater, because the upper part of the mud will dry rapidly by absorption of water into the dry fill. This was one of the major reasons why the writer endeavored in every way not to remove the dry crust.

Where the stabilized surface of the runways has been completed for six to ten months the settlement has been sufficiently uniform so that few water pockets have formed on the surface, despite the fact that the crown of the runways is only 9 in. in a width of 150 ft. However, where one runway crosses three main sewers that were built previously upon a pile foundation, and over an old buried concrete bulkhead, there is an evident settlement of nearly 3 in. No other measurements can be made because the surface of the stabilization was not sufficiently exact to permit measurement of the small amount of settlement.
